INDEX.

Actinograph. The	390	Compressed Gas. Use of	129	Economy in the Dark Room	678, 710
Albumen-Bromide Paper. By E. Graham	295	Compressed Gas in Cylinders. By J. A. Fleming	135	EDITORIAL TABLE:—	
Alkaline Solutions. Strength of...	294, 310	Compressed Gas in Cylinders. By W. I. Chadwick	101, 115	American Annual, 1890	10
Allochromic Forms of Silver. By M. Carey Lea	444, 461, 478, 484, 573, 621	Concurrent Development and Fixation. By W. D. Richmond	827	American Lantern Sets and Lectures. By F. York & Son	166
Amateur. Facilities for Photographing	45	Continuance of Action of Light. By T. Bedding	619	A New Principle in Heliochromy. By F. E. Ives	185
Amateur Dark Room Appliances	709, 726, 742, 759	CONVENTION PROCEEDINGS:—		Anthony's Half-Century in Photographic Apparatus	502
Amateurism	722, 739, 755, 787, 819, 851	Address by President, A. Pringle	351	Anthony's Lilliput Camera	271
Amateurs and Tuning. By C. B. Barnes	795	Identifying and Reconstituting Paper. By A. Hasdon	570	Barnett's Film Carrier and Flexible Negative Films	767
American Men and Matters	69, 129	False Rendering of Images by Misapplication of Lenses. By T. R. Dallmeyer	354	By the London Stereoscopic Company	767
American Practices	26	For Talbot's Early Experiments. By Friese Greene	585	Bolton's Film Carriers	447
Apprentices	151	Lenses for Hand or Detective Camera. By J. Traill Taylor	513	Celluloid Films	512
Argentine Republic. Photography in	451	Method of Ascertaining Comparative Printing Value of Negatives. By E. Danmore	370	Convention Group. By Friese Greene	705
Art in Relation to Photography. By W. Cobb	164, 182	Orthochromatic Photography with Gelatine Plates. By C. H. Rothamby	571	Convention Group. By Richard Keene	689
Art. Its bearings on Photography. By John Fisher	415	Past and Present. By W. M. Ashman	367	Der Kollie-Druck. By Dr. Liesegang	395
Assignment, its Nature and Effects	81	Photo-mechanical Processes. By T. Boles	598, 610	Der Licht-Druck. By Dr. Schumann	395
Analysis	171	Report upon Lens Standards	574	Dictionary of Photography. By E. J. Wall	163
Antony on Men and Things	326	Convention. Report on, to Photographic Club	651	The Amateur Photographer. By R. Talbot	767
Antony and Charnwood Forest. By R. Keene	361	Copying Paintings	15, 45	The Photogrammetrie. By Dr. C. Coppel	767
Bichromate Dyeing. Remedy for	316	Copying Paintings. By W. H. Davies	300, 364, 424, 491	The Photographie mit Bromsilber-Gelatine. By L. David and Charles Seilik	767
Bichromate of Potash. Physiological Effects of	173, 310	Copying Woodcuts for the Lantern	409	Electric Light for the Milliner. By A. F. Guy	511
Blindness. By W. H. Sherman	604	Copyright. Law of. By J. Harris Stone	214	Fallowfield's Mounts	40
Blindness on Prints	609	Crystal Palace Exhibition	198	Fleming's Explosive Gas Tester	161
British Association:—		Customs House Regulations	371	Flourens's Monochromatic Lamp	109
Captain Abney's Opening Address	621, 634	Cycling and Photography	14	Gode's Coloured Glasses for Orthochromatic Photography	417
Bromide Prints. Experiments with. By Adolphe H. Levy	694	Daguerre. Memorials of. By W. Lang	705	Hart's Improved Flash Lamp	298
Brown Powder on Mounts. By C. I. Burton	142	Daguerreotype. By W. T. Horton	150, 184	International Annual of Anthony's Bulletin	416
Buck, T. Dinner to	473	Daguerreotype. Discovery of the. By L. H. Landy	429	Introductory Lessons in Quantitative Analysis. By J. Mills and B. North	718
Calculating Exposures. By Sir D. Salmons	441	Dallmeyer's Diaphragm Shutter	61	Lehrbuch der Photographischen Chemie. By A. Lainer	718
Camera. Choosing a	81	Dangerous Hypo Eliminators	677	Magnesiumlichtes in der Photographie. By Dr. Max Müller	767
Camera. Noth's (1894). By W. Lang	150	Darkened Silver Chloride Not an Oxy-Chloride. By M. Carey Lea	814	Marion's Focusing Eyepiece	767
Camera Slide. How?	36	Day in the Printing Room. By G. H. E. Sutton	799	Marion's "Norner" Variometer	800
Camera Mount. By John Harner	606	Decimal System versus Confusion in Weights and Measures	174	Marine Photographs. By J. E. Gould	793
Camera. The Largest in the World. By E. H. Supple	108	Deer Stalking with a Camera. By W. P. Adams	617	Mason's Artist Mount	621
Camera. Watson's New	10	Defects in Portraits. Novel Means of Remedying. By E. Wallace	819	Naturalistic Photography. By Dr. P. H. Emerson	221
Camera Surface. Photographing. By W. H. Davies	615	Density of Intensified Negatives. By Captain Abney	777	Newton's Infraction Gratings	481
Carb. By E. Danmore	459	Density with Hydroquinone	453	Our Home in Azyron. By G. E. Davies and Mrs. Bromhall	831
Chalybeate of Potassium Chlorate and Manganese Dioxide. By E. H. Warren	39	Destruction or Removal of the Image	507, 614	Photographie mit Bromsilber-Gelatine. By Dr. J. M. Eder	718
Caustic Alkalies. Solutions of	365	Detective Cameras	151, 163, 158	Picture Making by Photography. By H. P. Robinson	542
Celluloid	609	Detective Camera. Intelligent Use of. By H. Wilkinson	605	Processes of Paper Photography. By W. K. Burton	542
Celluloid Films for Lanterns. By W. J. Harrison	813	Detective Cameras. By A. Black	412	Reaching Negatives and Finishing and Colouring Photographs. By Robert Johnson	289
Celluloid. Positives on	773	Detective Cameras. By W. P. Adams	763	Salomon's Photographic Slide Rule	391
Chemical Vignettes. By R. Morrison	157	Deterioration of Dry Plates. By T. N. Armstrong	509, 519	Scotland's Convention Group at Kew	691
Chemistry of Photography. By J. C. Wiggins	349	Developer. Repeated Use of. By W. B. Bolton	122	Southern Life and Scenery. By O. P. Havens	830
Children. A Corner of. By R. Keene	607	Developers. Comparative Experiments with. By E. Himly	378	Stereoscopic Transparencies. By W. I. Chadwick	705
Cloud Effects. By E. Danmore	339	Developers. Similarity of Action of Different	264	Stewart's Premier Lantern	718
Coll. Means of Producing	357	Development. A Chat on. By W. Schmidt	181	Sun Artists	705
Colloidal-Bromide Emulsion. By F. C. Beach	25, 40, 74, 80, 103	Development. By J. Coddett	219	Waller's New Series of Portrait Apparatus	240
Colloidal-Gelatin. By E. Graham	619	Development by Separate Solutions. By D. Bachrach	58	The Aplus Revolving Spirit Level	620
Colloid Emulsion. Unwashed	661	Developable	532	The Chemistry of Photography. By Professor R. Meldola	472
Coloured Photographs. By R. Barrett	411, 457, 474, 507, 558, 600, 617, 648, 662, 697, 730, 746	Diaphanoscopes. The. By R. H. Bow	296	The "Facile" Detective Camera	391
Colours: No Relation to Photography. By Friese Greene	439	Direct Large Portraits. By G. H. Croughton	539	The "Gem" Drop Shutter	393
Combination Enlargements	97	Dissolver for Single Lantern. By T. Galliver	235	The "Perfection" Dark Room Candle Lamp	316
Combination Printing	693	Double Printing in Developing Processes	138	The Wild North Coast. By A. Johnston	511
Combining Two or More Negatives	278, 310	Dutch Silver Economy. By W. H. Harrison	75, 107	Thornton-Pickard Time Shutter	782
Comparison of Developers. By Lyonel Clark	293	Early Days of Amateur Photography. By H. J. Newton	180	Yerer's Practical Amateur Photography	413
Comparison of Eikonogen and Pyrogallol. By H. Eikonogen	792			Places in Belgium. London Stereoscopic Company	60

	PAGE		PAGE
Illustrative Photography	645	Leads. An Improved	325
Illustrative Prints	64	Lens. Formula for finding Effective Aperture of	53
Instantaneous Exposures	604	Lenses	313
Instantaneous Photography. By R. E. M. Bain	604	Lenses. By Walter Griffiths	703
Instantaneous Work. By T. N. Armstrong	6, 23, 68	Lenses. Effect of Diminishing the Diameter of	193
Instructing the Public. By A. Bogardus	87	Lenses. Effect of Reversing Single	326
Intensification by Mercury. By E. Dunmore	489	Lenses—Photographic and Microscopic. By H. C. Henry	237
Intensifying Thin Negatives	797	Lenses. Spherical Aberration in. By E. M. Nelson	103
Irregular Development with Hydroquinone	341	Leases. The Construction of. By Conrad Bock	104, 125
Irregular Toning of Transparencies	405	Lighting the Sitter. By A. W. Scott	178, 440, 523
Jack and I in Norway. By Mark Onte	413, 428, 446, 462, 477, 492, 509, 527, 539, 560, 575, 590	Light: its Chemical Action. By P. Brahan	92
Japanese Journal	247	Light Lenses and Stops. By John Edmonds	603
Japan with a Camera. Through. By W. K. Burton	414, 479, 494, 526, 540, 575, 607, 622	Lightning. How to Photograph	491
Jena Optical Glass	150	Light. Photographic Standard of	629
Kent. A Day's Outing with a Camera	528	Limb-light Matters. By Lewis Wright	546
Kristoline	132	Line Drawings. Processes for Copying. By T. Scott	476
Landscape Art. By W. H. Davies	701	Local Development	305
Landscapes without Figures. By T. M. Brownrigg	483	London Stereo-Company's Factories	471, 498
Lantern. Early History of	15	Luekhart on Retouching	747
Lantern. Management of. By P. H. Phillips	650	Marion's Show Room	426
Lantern Slides. Development of. By Abel Heywood	70	Marking Slides for the Lantern	791
Lantern Slide Competitions	222	Mercantile Intensification. By W. H. D.	217
Lantern Slide Making. By E. H. Jaques	617	Mercurial Salts. Reaction of on Intensifiers	33
Lantern Slides. Binding and Framing. By R. H. Bow	285	Metric System. Report of Photographic Club	353
Lantern Slides. By C. B. Lloyd	632, 714, 760	Metric System. The	359
Lantern Slides. Easy Way of Making. By H. S. Starnes	288, 282, 299, 314	Metric System. Translation of English Formulae into the. By A. Cowan	395
Lantern Slides. Sorting	94	Mixed Gases. Dangers of. By G. Smith	123
Latent Image and Development. By C. I. Burton	215	Monopoly and Trusts. By E. K. Hough	693
Lausanne. By Canon St. Vincent Beechey	656	Mounting Prints. By E. Wallace	474
Lantern Improvements	840	Mounting Prints. Three Systems of	153
Lantern Microscope. Leach's Improved	811	Myhrbridge at the London Institution. By W. P. Adams	826
Lantern Slide. A Mysterious	837	Naturalistic Photography	563, 579, 595, 610, 658, 674
LEADERS:—		Nebula. Discoveries in, by Photography. By E. S. Holden	639
Albumen Process. The	470	Nebulae. Photographing the. By A. A. Common	57, 72
Alkaline Solutions. Strength of	294, 310	Negative Image. By T. Belding	684, 716, 732, 776
Altitudes. Facilities for Photographing	65	Negatives. Standard Characteristics in	65
Amateur Dark Room Appliances	709, 726, 742, 758		
Apprentices	153		
Astigmatism, its Nature and Effects	81		
Bichromate of Potash. Physiological Effects of	173, 209		
Black Vignettes and Deuter Effects	789		
Blaters on Prints	629		
Camera. Choosing a	81		
Caustic Alkalies. Solutions of	535		
Celluloid	489		
Celluloid. Positives on	773		
Ceramic Photography	631		
Chromotype Process. The	533		
Cold. Means of Producing	357		
Collodion Emulsion. Unwashed	661		
Collodion Transfers	693		
Combination Enlargements	97		
Combining Two or More Negatives	278, 310		
Crystal Palace Exhibition	193		
Cycling and Photography	18		
Dangerous Hypo Illuminators	677		
Dermal System versus Confusion in Weights and Measures	174		
Density with Hydroquinone	453		
Destruction or Removal of the Image	597, 614		
Double Printing in Developing Processes	138		
Ebancron Process	662		
Economy in the Dark Room	678, 710		
Exhibition. Photographic Society's	645		
Explosive Silver and Iron Compounds	137		
Exposure by Rule	517		
Ferrus Oxalate	358		
Fire Insurance and Photographers	406		
Flashing Compounds	805		
Focus. Depth of, in Portraiture	260		
Focusing. Appliances for Facilitating	245		
French Photographic Congress	485, 501, 534		
Fulminating Compounds	173		
Fossil Young and American Fossils	171		
Gas Explosion	97		
Gas Explosions. By G. R. Baker	109		
Gelatin Plates rendered Conductive	435		
Glass. Jena Optical. By A. Muthé	627		
Gold and Silver Salts. Home-made	613, 646		
Gum Bal. By C. I. Burton	313		
Gum Bismuth. By U. B. Burton	411		
Grained Surfaces for Zinc Etching. By W. T. Will	308		
Groths of Hens. By G. R. Baker	733, 740		
Gummed Glass Plates for Negatives. By J. A. Forrest	261, 260		
Hand Camera	161		
Hand. Means of Printing	780		
Heliography. A History. By F. K. Lee	731		
Heliography. A. L.	267		
How to Enlarge. By F. Eady	529		
Hydroquinone and Sulphurous Acid	10		
Hydroquinone. By J. W. H. Jones	142, 131		
Hydroquinone. By T. Charters White	124		
Hydroquinone. Composition of	215		
Hydroquinone. Duration of	130		
Hydroquinone. Valuation of. By W. R. Bolton	174		
Hydroquinone. White and Permanent. By Alfonso Tanager	223		
Hydroquinone. Valuation of. By A. M. Levy	164		
Hydroquinone. Valuation	43		
Hypo. Illuminators from Prints. By W. K. Burton	241		
Hypo Solutions	209, 260		

Supplement. Jan. 10, 1894.	PAGE	PAGE	PAGE
EXHAUSTED PROCESSES:—		Portrait Painting applied to Photography. By G. J. Serrell ...	489
Albuen Process. The ...	470	Portraits by Photography. By G. L. Hurl ...	576
Black Vignettes and Denser Effects ...	789	Postal Damage to Photographs ...	537
Chromic Photography ...	631	Post Office and Photographs ...	421
Chromotype Process. The ...	535	Practice and Theory. By E. Dunmore ...	618, 634
Collodion Transfers ...	681	Preservation of Pyrogallol Solutions. By C. I. Burton ...	329
Emulsion Process ...	682	Printing and Other Matters. By E. Dunmore ...	8
Glass Positives: Albustine Process ...	725	Printing Processes. By E. Seyd ...	443
Lanthotype and Contotype ...	595	Printing Room Materials ...	582
Negatives Produced from Negatives ...	757	Process Block Making at Paris Exhibition ...	841
Photo-etching ...	693	Process Printing. By W. H. Davies ...	684
Powder Process. The ...	502	Process Work in the French Exhibition ...	468
Stannotype. The ...	437	Projecting Lifelike Motions. By G. R. Baker ...	316
Warner's New Process ...	498	Proofs and Retouchings ...	770
Neglected Processes.—Why Neglected ...	623	Psychic Photography ...	13, 180, 219
Merrill's Rapid Collodion Process ...	229	Pyro and Hydroquinone Development ...	422
Norway ...	198	Pyro Developers versus Gelatine Plates ...	117
Norway. Photographing in ...	114, 134	Quarterly Report on Progress. By J. A. Forrest ...	453
Objective. Photographic. By E. Banach ...	71, 99, 102	Quinol ...	226
Orthochromatic Plates for Copying Oil Paintings. By E. E. Armstrong ...	345, 364, 410	Recovering Bromide from Waste Plates and Emulsions ...	373
Ownership of Negative ...	31, 45, 46	Red End of Spectrum. Photography at. By Colonel Waterhouse ...	685
Printing Plates ...	305	Redevelopment. An Experience. By T. Bedding ...	825
Pyroxyline for Flash Lights. By W. B. Bolton ...	363	Reflections on Photographers. By E. Dunmore ...	530
Plates in Photography ...	277	Residues and Savings. General ...	549
Portulacite Lanterns. By G. R. Baker ...	793	Residues (Print Washings) ...	517
Pyrogallol Hydroquinone. By Martin Freund ...	343	Residues (Sulphides) ...	495
Platino in a Photograph ...	315, 468	Review of Photographic Progress. Quarter's. By J. A. Forrest ...	270
Photo-galvanographic Process. Pretsch's ...	273	Retouching. Archbishop of York on ...	116
Photographers' Defence Union ...	12	Retouching. By W. Wilkinson ...	300
Photographic Blue Book. By W. Lang ...	702	Reversing Negatives by the Mirror ...	557
Photographic Lenses as Telescope Objectives ...	437	Ring and Curve Systems on Allotropic Silver. By J. K. Talloch ...	638
Photographing Interiors ...	305, 741, 774, 807, 828	Robinson's Photographs at the Camera Club ...	731
Photographing the Highest Mountain. By T. Hoff ...	9	Round the Fleet with an Instanograph ...	557
Photographs Plain or Coloured. By E. Dunmore ...	700	Saturated Solutions ...	51
Photographs taken with the Eye, &c. By Priess ...	54	Sawyer. The Late J. E. ...	50
Photography and Crime. By T. Coan ...	508	Science and Art. By P. H. Emerson ...	252, 269
Photography and the Law of Error. By Captain Abern ...	315, 324	Sensitized Paper. Defects in ...	17, 49
Photography in Mount Moria. By Talbot Archer ...	55	Sensitiveness of Plates. Method of Determining Relative. By W. H. Pickering ...	321
Photogravure Processes. By E. Edwards ...	432	Sensitometry. By W. B. Bolton ...	809, 840
Photogravure. The Limits of. By A. Dawson ...	393, 395	Shadowless Mounts. By W. H. Davies ...	382
Photo-lithography. By W. T. Wilkinson ...	396	Shadows and Photography ...	62, 90
Photo-mechanical Jottings. By W. T. Wilkinson ...	94, 137	Sharpness of Portraits Influencing Effect. By Bruce Seemann ...	580
Photo-mechanical Work. Dry Plates in. By W. T. Wilkinson ...	347	Sheaths for Dry Plates ...	451
Photo-micrography. By Adolf Schalte ...	352, 386, 391	Shutter. The Best Position for. By T. Everett ...	85
Photo-micrography. By A. Pringle ...	217	Shutter. The Grimestone ...	80
Photopl ...	604	Sidereal Photographs. Defects in ...	399
Photopl Art. Relation of Photography to. By John ...	215	Sidereal Photographs. Defects in. By C. Piazzi Smyth ...	418

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1496. VOL. XXXVI.—JANUARY 4, 1889.

THE USE OF THE SULPHITES.

In our article upon this subject three weeks ago we referred to some experiments we were making with regard to the proportions in which sulphite of soda was added to the developing solution, and we have now sufficient memoranda to be of interest. In using this salt, as its price is not great, we feel that it is desirable to recommend the employment on all occasions of the pure crystals for developing purposes. We have often used the commercial article, and been satisfied with its action, but uniformity is always advisable where possible; it will be ensured by using the recrystallised sulphite. We have used it also both with and without the addition of acid, and could perceive no difference, so that, as regards acid, it becomes merely a question of how long the solution of pyro is likely to be required to keep. A few weeks, and it will not need acid; but if it is intended to last for months, let acid be employed; but, above all, it is essential that for every-day work the "pyro" solution should be uniform both as to whether it is acidified or not, and as to the proportion of acid present. Many persons prefer to use acid sulphite of soda instead of free acid, but our preference is given to citric acid, both on account of our preferring an acid that does not at all set upon the image, and also of the tendency of solution of acid sulphite to absorb oxygen, and become changed into sulphate, when the preservative action as acid would be as nothing.

These preliminaries stated, we may discuss the results obtained which, as they are the outcome of a very large number of experiments, may be thoroughly relied upon. Our main object was to ascertain for ourselves the best working proportions for every-day development, and if we arrive at no new conclusions, alter no old formulæ, we, at least, can give added weight to their claims. We started with a developer containing sulphite to the extent of one grain for each grain of pyro, and this strength was gradually increased grain by grain till the last solution used contained twelve grains of sulphite to each grain of pyro, a proportion beyond which it is quite useless to go.

The grain-to-grain pyro gave results very much in favour of the use of sulphite, the yellow colour of the negative was greatly reduced, and the solution did not discolour so rapidly. Two grains to one of pyro was still better—yellowness greatly reduced, but still not giving "wet-plate" character. Three grains better still, but the whole benefit sulphite was capable of imparting not yet obtained. Four grains to one of pyro—and this, be it noted, is the original formula Mr Berkeley gave

to the world when he first made public the benefit obtainable from the use of sulphite—we found to give an excellent working solution, giving a good proportion, but not all, of the benefits obtainable, and one that was a vast improvement on all the rest. From five to six grains were still better, and that we looked upon as a practical limit for a working formula, as, although under some conditions—as, for example, greatly prolonged development and maximum amount of ammonia added—complete freedom from yellowness was not obtained, in by far the larger number of cases the fixed negative was all that could be desired for cleanness and "wet-plate" character. For the present we have fixed upon the proportion of six grains of sulphite of soda to each grain of pyro employed as the formula for our own general developing work. There is one good reason for adhering to a high proportion, and that is the increased power of using the solution with advantage for more plates than one. We have developed three plates in succession in the same solution without perceiving any but the slightest difference between the first and the last as regards yellowness, a condition that does not obtain with lower proportions of sulphite. When an open measure containing used solution was left exposed to the air for twenty-four hours it remained clear, and did not arrive at the depth of colour the one-to-one proportion attained in half an hour.

Another singular quality was perceptible when the highest strength was used—namely, a distinctly red hue imparted to the solution, more particularly discernible when the colour was observed in white vessels. So much was this changed hue discernible that a white jug containing a small quantity at the bottom that had been left for one day was brought to us with an inquiry as to what the red liquid was, our questioner being quite familiar with the ordinary aspect of oxidised "pyro" solution. We noticed in the *Chemical News' précis* of foreign chemical news a chemist having observed and published the fact that dilute solutions of copper gave a rose-coloured solution with saturated solution of sulphite of soda, to which a little pyrogallol had been added; two other chemists, while agreeing with these results, found also that the reaction is not characteristic of copper, being producible with dilute aqueous solutions of most metallic salts, and even with distilled water. As our own above-cited experiments show, the production of this pink colour follows oxidation, and is higher the greater the amount of sulphite present in comparison with pyro.

In conclusion, we may say that we have never found any objectionable action in the use of sulphite in the pyro ammonia developer, but we have made no exact comparative

trials. We purpose at some future time making tests in this direction, though we anticipate results of an entirely negative character.

A VENTILATING DARK-ROOM WINDOW.

Although the alkaline carbonates are gradually coming into use instead of ammonia for development, there is no doubt the latter still remains, and will continue to be, the favourite in spite of its volatility and the troubles it brings with it in consequence of that quality. We have in the present article nothing to do with the chemical side of the question—that is, the uncertainty that may arise from the rapidly varying strength of the unstable solution—but merely look at the sanitary considerations. Many operators, some far more than others, suffer greatly from the effects of the fumes of ammonia given off in the developing room; and where the process of development is a continuous one, lasting over several hours at a stretch, as is frequently the case in large establishments, it is by no means difficult to conceive that the permanent injury to health, as well as the temporary discomfort so caused, may be very considerable. Any means of alleviating the distress produced in this manner may therefore be welcomed.

Some time ago, when paying a visit of inspection to Messrs. Valentine & Son's extensive works at Dundee, we were greatly struck with a feature to which Mr. Valentine himself attached some importance in their developing room, namely, the provision made for carrying off immediately the fumes of ammonia rising from the developing dish, and this so effectually that the operator need never even smell the alkali. In an extensive establishment like the one we mention, where undeveloped plates are sent in daily by a large staff of outdoor operators, the process of development is naturally going on "from early morn to dewy eve," and without some adequate means of freeing the atmosphere of the work room of the noxious fumes given off from the numerous evaporating surfaces simultaneously exposed, the place would soon become unbearable.

The remedy in this case consisted in a current of air being induced to pass over the developing sink in the direction from the operator, carrying the ammonia fumes directly into communication with the open air, and thus not only freeing the atmosphere of the room of the injurious alkali, but also clearing it of all other noxious matter. We do not recollect the exact details of Messrs. Valentine's arrangement, or how the air current was induced, but we had ample evidence of its efficiency. A few days ago we saw, however, in an amateur laboratory, a similar arrangement of great simplicity, which may very well be utilised either on a small or large scale without any great expense.

In the arrangement referred to the air current is induced by a gas flame, which also serves the purpose of lighting the room—not necessarily, for daylight may be employed if preferred; but many experienced workers prefer to rely upon artificial light, as being more uniform, and consequently leading to more trustworthy results. When artificial light is employed, whether it be gas or oil, there need, therefore, be no additional expense; but even if daylight be used, the extra cost of gas or oil for the mere purpose of setting up a current will not be a serious matter.

A double casing to the lower portion of the window, forming a sort of "lantern" about ten inches or a foot deep, constitutes the main part of the system. The front of the lantern may be "glazed" with any medium suitable for artificial light,

while the back or window proper may have an additional thickness of non-actinic colour to render it safe for daylight, or may be left clear if daylight is not utilised. Along the lower front edge of the casing is an opening to admit air which supplies "food" for the lamp inside, and at the same time draws off the vitiated air from the room. The top of the lantern is provided with a tube, which should preferably communicate with the open air, or be run into the chimney if such be accessible; but if a ventilator of the ordinary character be fixed in the upper portion of the room, the exit tube may discharge its current into the room itself.

It is true this kind of arrangement does not act as a very powerful ventilator in the general sense, but at any rate it carries the ammonia fumes away from the operator, and delivers them at a distance, whence they cannot reach him without being considerably and sensibly diluted. We should, however, recommend the exit tube to be carried through the wall either into the "open" or into a chimney where possible, and to prevent any down draught a suitable cowl should be provided. It is needless to say that the nearer the air inlet is to the ordinary position of the developing dish when in use, the better will be the ventilating action.

SILVER PRINTS NOW CONTRASTED WITH THOSE OF THIRTY YEARS AGO.

At the commencement of the new year it may not be amiss to "take stock" of the conditions under which our finished pictures are now produced, and compare them with those which existed in times long past, and see what, if any, improvements have been effected. Let us bark back, say, thirty years. It is an even number, and will take us to the year 1859. The only method of printing then in use was that on albumenised paper, for at that period salted paper had practically become obsolete. The albumenised paper of those days was quite a different thing from what it is now. Its surface, in comparison with the present article, would be considered matt. For it was not until the *carte* picture became popular that the very highly glazed papers were adopted.

Fading or yellowed prints were known at that period, a cry was raised for a permanent process, and in course of time the carbon, the Woodburytype, the collotype, and the chromotype processes were introduced. As each of these processes were brought forward it was predicted by the sanguine that silver printing had received its death blow. However, it survived, and still survives. For a time the platinotype process made but little headway, as its tones were only partially admired. However, taste on this point has undergone a radical change, and platinotype has now become firmly established as a process of the future, and its results are permanent. And we have the gelatinobromide and the gelatino-chloride processes, which also yield excellent results, and at the same time are undoubtedly the most permanent of silver printing processes. In face of all these different methods of printing, there is no gainsaying the fact that out of the total number of photographs now produced only a very small percentage of them are other than albumenised paper prints. Silver printing on albumen paper still holds sway, for what reason it is not our present purpose to inquire; it is sufficient to know that it does, and in all probability it will continue to do so for some time to come.

Seeing that the same method of printing that was in use thirty years ago is still employed naturally leads one to inquire

of the prints now made are superior in quality or are more permanent than those which used to be produced at the date mentioned. With reference to the excellence of the work, taking into consideration the quality now conferred upon the negative by retouching, we say there is no improvement, and, what is more, many of the deep rich tones of old are now unattainable. As regards permanency we reply there has been a retrogression, and assert that the majority of the silver prints produced at the present time are far more evanescent than those which used to be made three decades back. It is an unpleasant admission to make, but it is nevertheless the fact, notwithstanding that, as a rule, more care is, or is supposed to be, bestowed upon the work.

It would be useless to deny that photographs faded in those days; but fading as it is now met with, often within a month or two, was a thing unknown. We have before us as we write a couple of portraits—different positions—of the same sitter, issued at the same time, only a few months ago, from one of the leading London houses whose prices are about the highest in the profession; one has faded badly, though the other is unchanged. Such a circumstance as this used not to occur; now, unfortunately, it is by no means uncommon. When we look at the altered conditions under which the prints are now produced and finished from those which formerly existed, it is not difficult to account for much of the fugitiveness.

At the period referred to the paper was but slightly albumenised, though it was heavily salted; it was sensitised on a bath of twice or thrice the strength now employed. The negatives then made were exceedingly vigorous, far more so than any now in use; consequently, by the time the image was printed it consisted of a much larger proportion of reduced silver—which, of course, took more gold to tone it—than those produced under existing conditions. The image was formed to a large extent in the body of the paper; whereas now it is confined almost, if not entirely, to the albumen surface. The difference may be readily seen if a modern print and one of the date referred to be examined side by side by a strong transmitted light. It goes without saying that an image composed of a large body of the reduced metals will better withstand deleterious influences than one in which it exists in the most attenuated form possible.

At the present time ready sensitised papers are extensively employed, the majority of which contain still less silver than that prepared at home. With many of these papers, owing to their preparation, the sizing matter is removed in the fixing and washing operations, so that in the end the print becomes as porous as ordinary blotting paper. Now the removal of the size, in one respect, is an advantage, as it facilitates the elimination of the hypo. Indeed, at one time it was recommended to treat the prints with hot water to get rid of the size, so that the washing should be the more perfect. It is, however, easy to see that the extraction of the sizing material, instead of proving beneficial, may be just the reverse. For example, if an injurious mountant be used, or the picture be put upon a mount containing deleterious matter, the frail image, by reason of the porosity of the paper, will be brought into more intimate contact with the disturbing influence than if the paper retained its original impervious character.

Thirty years ago photographers were content to use plain white cardboard for their mounts, and pay a higher price for them than they now do for those of a far more pretentious appearance. The inside of these boards was composed of a good quality of paper—wood or straw pulp “middles” had not then been intro-

duced—while the outer covering was a paper usually free from impurities in a photographic sense, for hyposulphite of soda as an anti-chlor had not then become general. Consequently the mounts were inert, which is more than can be said of a very large proportion of those now supplied.

When each of these matters is taken into consideration it is not difficult to account for the fact that the prints issued now prove less stable than those made in former times. For it must be admitted, unpleasant though it be to do so, that during the last thirty years photography, so far as the stability of silver prints is concerned, has retrograded instead of advanced.

THOUGH a practical photographer is in no need of a course of instruction in analytical chemistry to enable him to succeed in dark room work, occasions do arise when a little knowledge of ordinary reactions would be useful to him. The need, or supposed need, of a variety of apparatus, and a large number of bottles of reagents, generally operates to prevent anything being attempted by one unskilled in chemistry. There has, however, been published lately a singular kind of process of analysis which involves little or no special apparatus, the reagents for which will be found in most dark rooms. “Chemically pure white filtering paper, having a close grain, is dipped in a ten per cent. solution of ferrocyanide of potassium, laid on a pane of glass, and dried in the open air, or, preferably, in a drying oven, at 150° Fahr. Then prepare a ten per cent. solution of neutral chromate of potassium, also one of bromide of potassium, and one of hyposulphite of sodium, and proceed with each as before.” So much for reagents. The apparatus is merely a small pipette made of a piece of glass tube, three-sixteenths of an inch diameter inside, drawn in a flame to a narrow orifice, the end being perfectly round; a small quantity of the liquid to be tested is taken up to this pipette and a drop allowed to fall on each of the pieces of prepared paper (which may be ruled off into squares so as to answer for a number of different solutions), and according to the colours and variations of the rings and haloes produced by the decomposition may the nature of the substances under examination be detected. A full account of the method appears in the *Chemical News* for the 14th ultimo, to which we would refer all interested for details of the colours, &c., produced.

THE excessive lowness of the temperature during the whole of last year was matter of common observation and discussion, especially among photographers, who were influenced, and by no means favourably, by it. At the last meeting of the Royal Meteorological Society the subject was brought forward in a paper by the Rev. T. A. Preston, M.A., F.R.Met.Soc., who gave full details as to the comparative extent of the universal reduction of average temperature in the British Isles. During the fifty-nine weeks ending the third week in October there were but four warm weeks in the north-west, and only five in the south-west, of England, whilst in the latter district there was not a single warm week between March 12 and October 22. The mean temperature was colder than had been observed for ten years, with the single exception of the north of Scotland. At Greenwich the temperature during the fourteen months was below the average on 312 days out of 427, and in July there was not a single warm day. The means for July 11 and 12 were colder by several degrees than those for March 9 and 10. We may surely be permitted to hope that the new year we have just entered upon may be more favourable to photographic interests; but the auguries are unfavourable, as 1888 ended and 1889 began with a fog, which even to long-suffering Londoners was of unusual and distressing density.

ONE of the latest results of astronomical photography is arousing as lively an interest as did the famous epoch-marking photograph by Mr. Common of the nebula in Orient when first exhibited, and again it is the portrait of a nebula that has proved the value of photography. This picture, by Mr. Isaac Roberts, was exhibited at the last meeting

of the Royal Astronomical Society, and its value was at once recognised by all present, while its technical merits won great admiration. The especial interest attaching to this particular photograph lies in the fact that it appears to show the actual formation of a system out of the vague form of a nebula.

In a recent number of the *Harvard College Observatory*, an important and interesting account of the methods employed in their observatory in nebulae searching is given. Instead of using—as is ordinarily done, and as Mr. Common and Mr. Isaac Roberts have done with such conspicuous success for depicting large nebulae—a telescope for photographing these interesting objects, an ordinary photographic lens is used. This, as we need scarcely state, acts far more quickly than the telescope object glass, and, in addition, embraces a much wider field of view, hence a larger space in the heavens can be searched and in a shorter time, and objects too dim to be picked up by the telescope may easily impress themselves upon the plate through the medium of a good photographic lens. Already some very valuable results have been obtained by these means.

THE present week has been an important one in many respects for astronomical observers, the solar eclipse of last Tuesday possessing the usual fascination the phenomena always exercises upon all who have command of important instruments. We have not heard of any English parties having set out to make observations, but America was amply represented. The great Lick telescope did not lose its custodians, as they stayed at the Observatory to photograph the various phases and observe the time of contact, though there the eclipse was only seen as a partial one. Several strong parties were made up for photographing the corona and making photometric and spectroscopic observations, and Professor Pickering, from Harvard, had no less than eight instruments in the field on the line of central eclipse. When full details are to hand we may anticipate a valuable harvest of facts to be garnered, as each time the phenomenon has been observed fresh facts and fresh precautions have been indicated to pave the way of the observer in the next occurrence of an eclipse. The present occasion was less favourable than some of its more recent predecessors, in that the duration of totality was only two minutes.

ECHOES.

THE perennial questions of copyright and the ownership of the negative have once more cropped up in different forms in the law courts, and yet again have been exercising the minds of photographers as well as the lay press. As usual, very varying comments and suggestions have been made—some new, some old; and it is only speaking the truth to say that photographers themselves are little more agreed on these subjects than the county court judges and other legal authorities who “ring the changes” so absurdly in their decisions. Here I may note, that in the leading article in last week's issue a fear is expressed that the Ashford decision in *Barnes versus Marston* will form a precedent. Of what use, however, are “precedents” in this matter, since, as the same article points out, three previous cases of a similar nature had been ruled differently, and were overruled by the wisdom of Ashford. It is true the editorial pen wrote that the decision “stands as a precedent,” &c., “until it is overruled;” but that may occur on the next court day in the same place.

The proposed trade protection society, if founded, would, I fear, prove quite powerless in the matter, however willing and energetic, so long as the present legal uncertainty exists; for what is the use of pleading “custom of the trade” when the judge arrays against that argument what he considers of infinitely greater value—his own common sense, or what he honestly imagines to be such. It is the fashion in many quarters to decry the “great unpaid” magistracy because of their sometimes erratic decisions, but I think that a careful survey of county court decisions, especially where technical points are involved—aye, and the decisions of the superior courts too—would disclose in an even greater degree the same kind of “happy-go-lucky” interpretation of the law, not only on the part of paid officials, but of those presumably specially educated for the purpose.

Photography, unfortunately, at present occupies no definite position of its own in the eyes of the law; it comes under the general heading of fine arts in the matter of copyright, but occupies such a particularly “back seat” that the compliment of even including it at all is a very questionable one. This being so, it is almost a matter of necessity that most of the cases that come before the courts depend upon the individual decisions or opinions of the judge, and upon precedents so established; and in attempting to legislate from the point of view that a photograph is a “work of art” of precisely the same character as a painting or drawing, the non-technical mind encounters so many difficulties that it is little wonder it occasionally wanders.

As regards the copyright in works of art, such as paintings or drawings, and in literary productions, the law, if not perfect, is at least comparatively distinct and intelligible, but not so in regard to photographs. For instance, the law does not say distinctly whether the copyright exists in the negative, or in the print, or in both; it decides that the copyright in a portrait or other work executed to order belongs, under certain conditions, to the party giving the order, and not to the photographer. But in the case of a photographer in a considerable way of business, employing assistants, and executing work on his own account for publication, it leaves matters rather ambiguous, as the decision in *Nottage versus Jackson* proves. Here the plaintiff brings an action for infringement of the copyright of a picture taken for purposes of publication by his firm through one of their operators; but he is nonsuited on the ground that the operator, and not himself, being the executant, in the operator is vested the copyright. Here, surely, is “tidings of great joy” to “sculptors’ ghosts,” to Jan van Beer’s numerous pupils, and to the race of artists’ assistants generally, if at least the same law is good outside photography.

Now, if photography cannot be properly legislated for in a general copyright act, or, rather, if it cannot be fairly treated when classed with works of art generally, let it be classed by itself, and have a clause or clauses specially devoted to it, and drawn up by an expert, in order to remove the “glorious uncertainty” that now exists. I do not know that this is a particularly hopeless solution of the difficulty, if the matter is properly taken up by photographers themselves. The Camera Club numbers among its members more than one who writes M.P. after his name, as belonging to the National Club at St. Stephen's, and if the Club desires to do good work in the interests of photographers generally, it could not select a better channel in which to direct its exertions. And I am sure that when another Copyright Bill is under discussion, some of the Camera Club “M.P.’s” might gain *éclat* by championing the cause, from their places “in the House,” of the art to which they have been attracted for their own pleasure.

The two questions of which I commenced to speak are too frequently mixed up and confused. The ownership of the negative is completely and entirely distinct from the copyright which exists in the print or finished picture. In the case of a painting the picture and the copyright may go together, or the copyright may be sold independently of the picture, in which case the owner of the original painting has no right to reproduce it. If the copyright pass into the hands of an engraver, who after a time again sells his right, I presume by the custom of the trade alone, and not by any right, the engraved plates existing would be delivered to the purchaser, though they do not in any way represent the copyright. In like manner a photographic negative is distinct from the copyright, but it is not the custom of the trade to part with it to the owner of the copyright or party for whom the photograph is executed. The reason of this difference between an engraving and a photograph is easily explained in a common sense way. The purchaser of the copyright of an engraving buys for the purpose of publication, to which end the engraved plates are of value to him; the purchaser of a photograph to order, in the great majority of cases, buys merely for private use, and the negative is to him useless except with the assistance of a competent photographer, hence the negative forms no part of the contract, but is simply used by the photographer as one of the “tools of his trade,” as it has been described.

In any future legislation on the subject it would therefore be well if the distinction between copyright and right to the negative be clearly recognised and emphasised by special treatment, for clearly to

the photographer the latter question is of at least equal importance to the other. Until, however, the matter is authoritatively settled, it is to be feared that similar cases to that at Ashford will continue periodically to crop up.

In an article on *Intensification*, by Mr. Thomas Bedding, I find a reference to the desirability of avoiding exposure to direct daylight when intensification with "mercuric bichloride" is being effected. *Par parenthèse*, Why mercuric chloride, Mr. Bedding? Is there a mercuric sub-chloride, or have you ever met with mercurous bichloride? But, *n'importe!* With regard to the avoidance of exposure to light, it is the first time, I think, I have ever seen any reference to the necessity, so I ask, Why? Is it, as I presume it must be, on account of some supposed sensibility of the bleached image to the action of light? If so, I would like to ask if it is necessary to avoid direct daylight when examining the old "alabastine" pictures? I have seen many of these and made a few of them in years that are gone, and only a few months ago I was shown a number that had been made as far back as "early in the fifties," which were as pearly white as they possibly could have been when "young." Never, in fact, do I remember to have seen or heard mentioned any instance of the darkening of such pictures by light. In *Watts's Dictionary of Chemistry*, I think, it is stated that chloride of silver darkens under the action of light, except in the presence of bichloride or other salt of mercury. If this be so, why avoid exposure?

The particular method of intensification, or rather the formula given in the article referred to, is new to me, and may be an improvement upon using a plain solution of bichloride; but to add potassium hydrate to cause turbidity, and to afterwards "clear" the solution with hydrochloric acid, appears to me a needlessly round-about way of adding potassium chloride as frequently practised, unless special advantage accrue from that mode of operating.

JENKINS.

SOLARISATION AND POLARISATION.

MOSELEY'S experiments with a prism of calcareous spar placed in front of the camera lens seemed to him to show that there was little, if any, difference between polarised chromatic light and common achromatic light, as far as their action on a silver salt goes. His exposures on the various coloured designs produced by polarised light led him to the same conclusion.

It will scarcely be denied, however, that the efficiency of white, blue, or violet light is almost immeasurably stronger in promoting that condition in a film of a sensitive silver salt, which first allows it to attract metal from the developer, than are those rays which we find to be the less refrangible. In fact, if one is not in a hurry, it is instructive to attempt—as the author has done—to obtain reversals and re-reversals by contact under a piece of ruby glass. Employing a spectroscope, the results are much the same, and in some respects we may look upon the production of a spectrum as the determination of the extent to which the separate elements of white light are liable to undergo alteration in their direction of vibration, for it will scarcely be denied that this liability must depend—where the undulations are assumed to be purely mechanical—almost as much on the direction of the vibration as upon amplitude and wave length, two conditions of the undulatory, either of which can scarcely be credited with identity of property or aim. It may be urged, indeed I believe it has been urged, that while the amplitude for all colours is constant, the wave length is variable, and *vice versa*; and in this case it is evidently useless to argue that the number alone of the strokes beating upon an organic or inorganic patient is sufficient to account, on frictional grounds only, for the difference of the powers of orange and blue light.

Before touching briefly upon electrical polarisation—a theory, not merely a hypothesis—let us try to get as clear an idea as possible of the broad distinctions which are known to exist between the actions of the different coloured rays.

To begin with, our appreciation of the mass of ponderable bodies teaches us that all matter is composed of more or less cohering molecules, with interstitial spaces occupied by—something. We talk at times of a vacuum, but in discoursing of light according to the correct prescribed method we are forced to confess that, while the more attenuated matter the greater the velocity of light; where matter, as a vehicle, is absent there can be no light, and no effect of light.

We say that the material wave front is essential to any exhibition of the motive cause, and is ever in advance of it. So also says the electrician! So also might the chemist say if he acknowledged that chemical affinity was the power, the element or compound the vehicle; and, indeed, this is exactly his position at the present moment. It is the electric potential and the conductivity which determine chemical combination and decomposition.

The primary colours are either three (red, yellow, and blue, and we can decompose none of them), or from twenty-three to thirty-three or more, in proportion as there are elements in the sun. According to the undulatory theory of light, the difference between sound, heat, visible light, and actinic or electrical energy is simply a difference of wave length, amplitude, and period; yet, *primâ facie*, there is no evidence forbidding the conclusion that the material either acts as a dielectric or conductor.

Admitting that the violet or blue rays are, more than any others, of metallic origin, and possess a reducing power, it remains to be seen, first, by what virtue they reduce; second, by what circumstances their characteristic action is modified.

It is scarcely to the point to object that it is the same ray or series of rays which reduce silver haloid salts that promote the combination of the metalloid chlorine and the metal hydrogen. The true point raised here is, Does the blue ray enhance or reduce the electro-positive nature of the hydrogen or the electro-negative character of the chlorine? That light, under conditions with which we are tolerably familiar, increases and diminishes the electrical potential between these elements we acknowledge; that it does both when the elements are pure and the light itself elementary is quite another question.

Broadly speaking, no recent experiments have negatived the deduction that for chloride, bromide, and iodide of silver, prepared in the utmost darkness attainable, the reducing action commences at F, attains its maximum at or about H, and gradually decreases towards the limits of the ultra-violet rays, and is nil for the rays of dark heat, and for the luminous rays from A to F.

With potassium bichromate, again, the action commences at E, and terminates at N. With tetrachloride of gold the action extends from E to I, the extent of the action being slight, but continuing spontaneously in the dark. "Hence we conclude that the reducing action exercised upon metallic salts is exclusively determined by the more refrangible rays, which on this account have been named exciting rays, while the heat and light-producing radiations, up to F, are absolutely inactive" (Jamin).

"Upon guaiacum, bitumen of Judea, and various essences, the action of light is inverse. Its tendency is to oxidise instead of to reduce." (These compounds, it will be observed, are organic and comparatively complex.) "Nevertheless experience has shown that it is the same series of rays which act. Thus gum guaiacum only begins to turn blue at H, and the action continues as far as P.

"Notwithstanding this, it must not be inferred that the calorific and luminous rays exert no influence. Let us once more take the case of the sensitive chloride of silver, but, instead of keeping it in the dark, let us expose it for a short time to white light, so as to produce a feeble but uniform discolouration throughout. Next let us bring a pure, real spectrum to bear upon a portion of this partially darkened film. It will now darken in every region of the spectrum, even from the infra red, and the luminous rays from A to H will be found to have acted. This time it is the less refrangible rays which have played their part in continuing and developing the impression initiated by the more refrangible rays, although in themselves incapable of starting the action. They do not excite, they continue, and have hence been named by Becquerel 'continuing' rays. It is to be remarked that they hasten or reveal the chemical action as they do in the case of phosphorescence.

"These rays do not oxidise white guaiacum, but when they are caused to fall upon guaiacum which has absorbed oxygen and become blue they disengage this gas and bleach the guaiacum. Instead of being oxidising agents of organic matter they are reducing agents, and their action is the inverse of the more refrangible rays" (Jamin).

In addition to this continuing, accelerating, or developing action, the luminous rays have also a destroying action on the effects produced by the blue and violet rays. Sir John Herschel and Claudet have abundantly proved this in the case of Daguerreotype plates, and A. M. Wilson, of Trinity, has, I think, while experimenting with modern dry plates and an astatic galvanometer under variously coloured lights, done much to establish the connexion between the action of orange and blue light, and that of positive and negative electricity; but it is in acting on a silver salt necessary to distinguish very carefully between these two actions of orange or red light, as intensifying or annulling the initiative action of the blue. As Claudet

has shown, if a daguerrotype plate, exposed, but undeveloped by mercury, be exposed under a red or yellow glass "for from 50 to 100 times the original insolation, it loses the property of condensing mercurial vapours."

Solarisation, as exemplified in the refusal of the portions of a sensitive silver salt which have undergone the longest exposure to attract the most of the silver deposited by the developer, is not therefore a phenomenon observable only with films of Ag Br, but of Ag I and Ag Cl also. The most point to be determined in the immediate future is therefore: Is it by virtue of a mechanical interference and polarisation of the light by particles and interstices in a constantly varying proportion that a given developer, no matter what, acts now normally, now abnormally? or is it due to a light-imparted alternating electrical polarisation of the opposite particles of the adjacent molecules?

There are one or two experiments, simple enough in themselves, which, carefully performed, would tend to lead us very much nearer to a solution of some vexed and vexatious questions in photography. For instance, the determination whether prolonged exposure to monochromatic light is capable of inducing "solarisation;" and whether the metallic coin which when left on a film in the dark for a few seconds permits of the development of a dark "image" of the areas in contact, would, if left on the film for a much longer period, develop a "reversal."

This second experiment may seem to some to have as much bearing on "light drawing" as has the experiment of writing with a "style" on a sensitive film through an interposed tissue less sensitive to light. Nevertheless, it is either to "Moser's images" or to "Shearing-stress" that we must look; in the first instance, for a rational explanation of the subject in hand; and while it is comparatively easy to see the connexion between electric potential and chemical affinity, it is difficult to reconcile a belief in the efficacy of a purely mechanical strain to separate the elements of a silver salt with a conviction that chemistry plays an important part in the formation of the "latent" image.

HUGH BRENNER.

(To be concluded.)

INSTANTANEOUS WORK.

X.

In my last I referred to a few subjects that were to be found in the vicinity of a farmyard, and endeavoured to show that such a locality furnished no end of pictures suitable for shutter work.

When operating on such, one of the most important points to observe is the securing of a sharp focus of the animal, bird, or whatever else is being photographed. To attain this end I have seen some novices go about the work in the most awkward, impulsive, and unbusiness-like manner, and to judge of their style of proceeding one would imagine that they were photographing human beings instead of the lower animals.

Now, with many that I have met in with a common way of going about this sort of work has been something like the following. No sooner does the novice see some fine specimen than he exclaims, "By Jove! I should like a photograph of that fellow!" and straightway, acting on the impulse of the moment, he proceeds immediately to unlimber and rig up his outfit, which done, he stealthily approaches what he is going to photograph, and planting his tripod, &c., in what he considers a suitable position and distance from the object, forthwith proceeds to wait about the focussing cloth and make other fussy operations, at the same time expecting and hoping that the animal he is about to take will act like a human being, and stand or sit still, as the case may be, just to oblige and let him have what he wants.

Often have I smiled to myself when being an eye-witness of such an operation, and I wonder where the photographer, be he amateur or professional, is who has not seen some such attempts to obtain a photograph. Up to a certain point, with some animals, their curiosity keeps them tolerably quiet and still, and this gives a novice the impression that he is going to succeed; but no sooner does he arrive at the focussing stage of the operation, and proceed to throw the black cloth over his head, than the curiosity which has up to this time kept the animal tolerably quiet gives place to a certain amount of shyness, and rising up or turning round, it shows its heels to the enthusiastic operator, and walks off without saying good-bye, leaving the operator with no small amount of annoyance, and who very likely will exclaim, "If I had not taken so long to get the blessed thing focussed I should have had him all right."

But, then, it is just in this focussing where an experienced outside operator shows to advantage over the novice, who merely goes about the job in a sort of ram-stam manner.

In contrast to such a way of going to work, were the novice to bear in mind the golden rule—and which applies to nearly all instances of animals in motion—*instead of bringing the camera to them, bring them to the camera*, he would have more successes than failures, provided the work was gone about with coolness and deliberation. Now, in following out this rule, it will at once be obvious that the subject must, in some way or other, be focussed beforehand, or just at the time of exposure. There are more ways than one of going about this. Perhaps the simplest, and, all being considered, the best plan is to select some spot and carefully adjust the focus for it; then, either by stratagem or simply leading or driving the animal, as the exigencies of the case may require, over this exact spot, and then expose. To effect such often requires the exercise of much patience and caution, but when these are brought into play success nearly always follows.

I remember one summer, when living for a few months at a farm, being asked by the farmer to photograph a fine bull he had grazing in the field. Now, this bull was not the quietest of animals, and although the farmer and the shepherd had no fear of going into the field and approaching him, I must say, on my part, I did not like the job at all of being near him with the camera when he was quietly driven up to me, and so I thought it best to use some little stratagem. After pondering over the situation I decided at last upon a little plan that succeeded admirably. To carry this out, however, required a considerable amount of courage. So, summoning the shepherd to my aid, I asked him to accompany me with his collie. Entering the field boldly with the camera focussed as nearly as I could judge for a distance of about fifteen yards, we came to a halt about fifty yards from the fence, and set up the tripod and camera in quite a daring way, and then, spotting a clump of grass right in a line between the bull and myself, I carefully focussed for this distance and bade my time, keeping the shepherd, with his collie between his knees, close beside me. It was not long before the bull began to pay us a little attention. No doubt he could not understand the camera, never having seen one before, and so his curiosity soon brought him in our direction, and whether or not he meant mischief I cannot say, but he kept quite steadily on his way until the exciting moment arrived, when, simultaneously with the firing of the shutter, the shepherd let go his collie, who at once rushed to the bull. Then I made off as fast as my legs would carry me, leaving the collie to fight it out with the bull. It was a harmless engagement, however, for soon the shepherd called off his dog, and the bull was left to himself. But I got my negative all right.

Now, I wonder how it would have been had I waited for the approach of the animal before setting about the focussing? Some may think this rather rash and dangerous work, but a sojourn of a month or two at a farm tends to imbue one with confidence when coming in contact with animals which otherwise he could not possess.

I remember, on another occasion, when being out on a prow with my little boy in the Highlands, falling in with an amateur who was doing his utmost to obtain some animal studies, and after hunting about he had at last found his heart's desire in the shape of some splendid "Highland stirks," one especially of which was lying down on the field, basking in the sunshine, at a distance of about fifty yards from the fence. Now, Highland stirks are not the most peaceful-looking animals, but, on the contrary, with most people their appearance gives rise to, more or less, a certain amount of fear, for their magnificent horns could do a power of damage if put to it, and I at once saw that my casual acquaintance was in somewhat of a quandary what to do, the distance of the animal from the fence being too great to allow of a picture of any size being obtained without coming to closer quarters. I could easily see that at first this gentleman was not a little shy at going over the fence and so approaching nearer to the animal: but on consulting me, and on my remarking that I did not think there would be any danger, he eventually summoned up courage and got over the fence with his apparatus and quietly approached the monster. All seemed to go well, just as I anticipated, till the focussing stage was reached, when the stirk coolly gathered himself together and marched off. On looking round about me I perceived that there were some stirks also in the next field, and that a hedge separated them, in the middle of which was a large gap, which the stirk that he was trying to photograph made straight for. I at once saw the opportunity, and so, on the return of the stranger back over the fence, I suggested to him to let me have a try. "Oh! it's no use," he replied; "they are sure to walk off just when you think you are getting them all right." It was evident to me the stranger had not had much experience in photographing animals. I, however, prevailed upon him after all to try

my little plan, which, after I explained it to him, he condescendingly approved of. I firmly believe, however, he would never have done so had I not consented to do the dangerous part of the operation, which was going into the next field with my little boy and quietly driving the sticks through the gap back into the field.

We accordingly set up the camera on the sunny side of the hedge, and focussed sharply on a spot about fifteen yards distant, over which the animals were bound to walk. Taking my little boy with me, I made a *détour* to the furthest end of the next field, and without making any violent noise, or in any way raising the spirit of the sticks, we just quietly approached first one, then another. At our approach they coolly gathered themselves up and made right for the gap, where the stranger stood in ambush with his camera. The result was that my friend was quite overjoyed with the success of the little operation, and declared he would know better in future how to go about cattle work.

Now, even in this driving of the game to the camera there is a "knack," and I cannot do better than just suggest to those who want to know the right way of going about it to try and see how cattle buyers go about their business when viewing animals at pasture in the country. Sometimes I think that the cattle themselves know when any one approaches them on business.

So much for bringing the cattle to the camera instead of the camera to the cattle. I know that sometimes there will crop up exceptional circumstances where it is not just so easy to arrange matters as one would like, but much can be done with forethought and the exercise of some little stratagem.

Who is there, when being in the vicinity of some farmyard, but has been struck with the funny appearance of the ducks, and to a photographer what an opportunity they offer for making a picture! It is not always an easy matter, however, to get a shot at them at a casual time, or just when an amateur might chance to be passing or about the farm, for the simple reason that Mrs. Duck very likely will not happen to be at home when so wanted. Very likely they will be at some distance from the pond, and when hunted for will be found grubbing in some field not far off.

To attempt, however, to drive them to their pond would only end in failure, for most likely by the time you got a remnant of them there they would be so raised as to offer but a poor picture of what they would otherwise show when enjoying their swim of their own accord.

Now ducks are funny things, and have some peculiar characteristics, like all other birds and animals, and when their little customs are known it is not a very difficult matter to secure a good picture of them pecking and pluming themselves in their native element.

Ducks, as a rule, are very regular in their habits, and not only always come home to tea, but in the early morning, in one sense, they resemble human beings, for they always go straight for their bath as soon as they are let out of the barn, or wherever else they sleep overnight.

Early morning, therefore, is the time to be about to secure the ducks. A little arrangement with the farm servant or poultry maid whereby the ducks are kept shut up a little longer than usual some morning is all that is necessary. This arranged, and the camera being rigged up in the desired place beforehand, the operator will not have long to wait for his visitors, for no sooner are they let out and free than it will be found that they make straight tracks for their pond. A stranger, however, should take care to conceal himself, or they may be a little shy in their approach for their swim. I remember the first time I tried such that I had to submit to somewhat of a failure, through being so near the pond with my camera, but the next morning I got what I wanted, and this by a little stratagem which was easily arranged.

The setting up of the camera gave no trouble. This done, and the trigger of the shutter having a long black thread attached to it, I had merely to hide myself from the view of the ducks. Now, to some it might appear a difficult thing to hide oneself in the vicinity of a duck pond. But such need not be the case. I merely got the farmer to help me to wheel out of the yard one of his carts with a sack of hay in it; so, jumping into the cart, I squatted down out of view and enjoyed the fun immensely. I did not require to try the next day. On a fine bright summer's morning some good fun can be had by keeping the ducks in confinement till about eight o'clock, when there is plenty of light to take them with a shutter.

So much for a few subjects that are to be met with around a farmyard. To any one desirous of spending a few days' rest, and who at the same time may be wishful of using his camera, I hardly know any place to equal the same for downright enjoyment, the planning out of the various little stratagems being to my mind not the least part of the fun.

T. N. ARMSTRONG.

ON CERTAIN SURFACES FEEBLY SENSITIVE TO LIGHT.

[A Communication to the Society of Amateur Photographers of New York.]

THE specimens which accompany this statement are suggestive, inasmuch as they tend to illustrate the widely extended range of photo-chemical action, and the part it plays in every-day phenomena. In thinking and speaking of substances sensitive to light, photographers and others are apt to remember only the haloid salts of silver; chromic acid, under restraint, acting on organic matter; asphaltum, and a few salts of iron and platinum: which short catalogue does, in fact, include all the sensitive bodies used in practical photography.

But, as every one knows, this list may be indefinitely extended (if the degree of sensitiveness be disregarded), and the accompanying specimens serve to show such extensions in certain directions. Broadly, the results should not be regarded as new, though in the manner of their preparation and presentation some novelty may be claimed for them.

On sheets Nos. 1 and 2, three samples of coloured commercial paper will be found, which are bleached by light, and which give, therefore, a negative when exposed under a negative. On sheets 2 and 3, exposed papers, coloured for the purpose with eosine and methyl violet, are exhibited; which likewise establish the fact that these colours under the luminous influence give rise to colourless compounds. But, though a great number of colours used in the arts are bleached by light more or less rapidly, this is by no means a universal rule. On sheet No. 1, a small piece of commercial orange paper is shown, part of which has been darkened by exposure. Specimens of paper coloured with picric acid will also be found on sheet No. 4, in which the darkening to a brown is very marked.

The duration of the exposures required to produce these photographic effects is very considerable when the change is carried to its maximum, varying from twenty to thirty-five or forty hours in direct sunlight, which was the only kind of exposure employed in these experiments. Such substances are, perhaps, from four hundred to eight hundred times less sensitive than chloride of silver paper. Indications of photo-chemical action are, however, visible in much less time. On sheet No. 2, a piece of eosine paper, exposed under two strips of black lace, shows a faint positive after half an hour. Also, on sheet No. 3, a piece of methyl violet paper similarly exposed shows the gradually increasing strength of the positive (by contrast) after one, two, or three hours.

The fact that printing and writing papers become brown by age is familiar to most persons; but that this change is essentially photographic is not a common belief. On sheet No. 5 will be found pieces of newspaper taken from the *New York Tribune*, the *Baltimore Sun*, and the *Washington Evening Star*, on which photographic images have been impressed by simple exposure under a dense negative. These papers were subjected to no preparatory treatment, establishing the fact that the newspapers we read daily are, probably, all printed on papers sensitive to light and adapted for the production of positive pictures. On sheets Nos. 6, 7, 8, and 9, such pictures will be found on *Evening Star* paper, made by direct exposure to the sun's rays, under collodion negatives. A fact of some significance is, that some of the experiments on *Evening Star* paper were made on sheets which had been very carefully washed before exposure. The washing was done by causing a very rapid film of water to flow over and under the paper at the same time for two and a half hours. The paper was then dried and exposed. This treatment did not seem to effect the sensitiveness of the paper to light, and the presumption would seem to be justifiable that the sensitive compounds present are not soluble in water. The time required to produce the maximum effect is about fifty hours, but this must often be exceeded if any part of the negative is in the least obscured by cloudiness. The colour produced by exposure on such papers is peculiar. When the paper is clean and in good condition, as in Nos. 6, 7, 8, and 9, a very pure golden bronzy colour is produced, which can be appreciated only in strong white light. I will not now discuss the nature of the resulting brown-yellow compound, except to say generally that it is not easily acted on by chemical re-agents, and that it undergoes a very peculiar darkening by the application of heat alone, as by ironing the paper bearing such a photograph with a moderately hot flat-iron. On sheet No. 8, a piece of paper is mounted with two tints on it longitudinally, half of which (divided across the tints) was heated in the way described, and which is, in consequence, much darkened. The print above it on the same sheet was also so developed or intensified.

Sheets Nos. 10, 11, and 12, have mounted upon them pieces of white pine, of different qualities, upon which photographs have been produced by exposures under stencil negatives, made by cutting openings in tin-foil, and pressing it into close contact with the sur-

face of the wood by means of a plate of glass properly clamped thereto. The exposure required to produce these photographic images varies from thirty to fifty or sixty hours. On sheet No. 13, a piece of poplar is shown, the picture on which was produced in twenty hours, for it seems probable that of all the woods in common use poplar is the most sensitive and gives the darkest colour when fully exposed. In making these experiments it is important to obtain a fresh surface on the wood, to effect which, in the case of an old piece, a good deal of the outside has often to be removed by the plane, for the penetration of the light is often considerable.

It seems probable that this darkening of wood (which is very commonly, though rather vaguely, attributed to the action of the air) is related to the photographic effect obtainable on printing papers. There are now hardly to be had without an admixture of wood pulp, and the present inquiry (inasmuch as it proves the phenomena to be strictly photographic) may have a practical bearing if it points to means which will keep printing papers white indefinitely.

On sheet No. 1, the bleaching action of light upon a dried leaf is exhibited, and on No. 5, a piece of parchment is mounted, which has also, though substantially white, become a little whiter where the light has acted. As far as it goes, this would tend to show that the "yellowing of parchments by age" is not a photo-chemical process. This parchment had a very long exposure.

As connected with this general subject, I would call to mind the investigations of Mr. Thomas Gaffield, of Boston, who established conclusively, more than twenty years ago, the slow effect of light on colourless glass, in gradually giving it colour, sometimes pinkish and sometimes yellow, the former being apparently due to a reoxidation of the reduced manganese employed to counteract the iron. These changes often required years for their completion.

Experiments, only just completed, tend to show that pure cellulose, in the form of the finest filtering paper, is not sensitive to light; at least, a constant exposure in a horizontal position to diffused and direct sunlight failed in two weeks to produce any perceptible change in colour. On the other hand, the same filtering paper, covered with picric acid and similarly exposed for the same time (about 140 hours of diffused and direct sunlight), gave a colouration as before, when used and calendered paper of the best quality was the kind treated with the acid. On sheet No. 14, two pieces of the above filtering paper, prepared with picric acid, and exposed horizontally as stated, will be found, but one of them has been washed in hot water till all the soluble matter has been removed. This treatment of the exposed print tends to raise the contrast by letting the darkened parts appear as on white paper; it also shows the insolubility of the darkened portions in hot water, the production of which was effected by light alone.

Simultaneously with the above exposures, another was made of the same duration and in the same way. This was the presentation of a thin stratum of commercial picric acid on glass, to the same illumination as that already mentioned, under a stencil tin-foil negative and a plate of glass covering the same. The picric acid was darkened as before very decidedly, though it would be difficult to exhibit the results in a satisfactory way at a meeting of the Society.

In concluding this paper, and to account for its incompleteness in certain ways, I may be permitted to explain that the investigation, the results of which are here given, was not undertaken with a practical purpose in view, but simply to determine the limits within which bodies may be properly described as sensitive or non-sensitive.

J. W. OSBORNE.

PRINTING AND OTHER MATTERS.

PRINTING what a simple process it is! Just place your paper on the negative, set it in the light till done, tone, fix, wash, and there you are! What could be more easy? The essence of simplicity. Yet how many find it so? I am not now speaking of professionals (who, by-the-by, are not always exempt from failures, simple as printing seems), but of those scores of amateurs who, with commendable spirit, are above being under any obligation to others for work supposed to emanate from themselves. They prefer saying, "Alone I did it," and right too. A man in real love with his work has a pride in doing it himself. He sees an effect, and wishes to produce it in a finished photograph as nearly as may be, and the first step is taking the negative; but he does not straightway go into mistakes over it, unless it will print a picture that will come equally up to his idea of what it should be. In the old wet-plate days the resulting print could be fairly reckoned on, and a negative could be changed as good, bad, or indifferent, with tolerable accuracy. But those days have passed, and we have gained considerably in comfort

but lost in certainty, to a degree. Unpromising negatives will surprise us by good results, and promising ones with just the contrary. So very little increase of density beyond the proper amount will result in chalkiness, and too little in flatness. In saying this I believe I only echo the opinion of most workers with gelatine plates, if the conditions vary much under which they were exposed. This is, however, merely introductory to "printing," the only real use of a negative, but as the qualities of the negative exercise considerable influence on the print it is necessary to notice them.

The wail of the amateur generally takes the form of "beastly paper," and "toning bath gone wrong;" but I think "beastly paper" has the preference. It is all very easy to blame the paper, which, no doubt, is sometimes in fault, but not nearly so often as represented. In all probability the fault lies in the user, who finds this the handiest way of excusing his want of knowledge. Ready sensitised paper is the kind almost universally used, and varies considerably in quality. Let it be borne in mind that all ready sensitised papers gradually deteriorate until they become worthless, therefore the sooner it is used after preparation the better. This deterioration varies with different samples, some retaining their good qualities much longer than others. The first sign of decadence is difficulty in toning. A paper may retain its purity of colour, and yet have become very difficult to use with satisfaction; this difficulty increases until it refuses to tone at all, and the prints turn out a dirty brown, although its sensitiveness to light seems very little altered. The first visible change is a slight yellowing, which in some samples of paper clears away in toning and fixing, and the finished proofs are none the worse for it.

It is unfortunate there is no guide to the purchaser as to the length of time the paper has been prepared; he has to take this all on trust. The brighter the surface the richer the print and the slower the toning; at the same time there is greater danger of blistering and cracking of the albumen if the prints are allowed to get very dry and curl; in washing the surface is also more easily damaged. The gloss, whether produced by extra thickness of albumen, or by a less absorbent surface of the paper, more in some samples than others, determines the final colour of the proofs. A dull paper gives colder tones, and plain paper the coldest of all. The rapidity with which it tones is generally in proportion to its lack of lustre, the plain paper being quickest, as the gilding, so to say, of the silver print is rapid in proportion to the unprotectedness of the metallic particles, and the richness of the image depends a good deal on the amount of albumen in which the silver is encased. Organic compounds of silver determine the colour, and the reduced metal its permanency. This indicates that a print consisting in a great measure of reduced silver, as the image on plain paper, would probably be more permanent than one of a richer colour—more dependent on organic matter. When prints fade, the delicate half tones go long before there is any perceptible alteration in the shadows, and as many of the beautifully rich and delicate prints now obtained on highly albumenised paper have a much larger proportion of half tones, they in all probability will fade more rapidly than the coarser black-and-white productions of years ago, which, when carefully prepared, set time and rough treatment at defiance; but, without going to such extremes, a good silver print from a fairly strong negative will, with ordinary care, last as long as a water colour at any rate, and stand more ill-usage.

I have now in my mind some silver prints that have been hanging in a full glare of light on a damp wall for many years. The last addition to them was made thirteen years ago, most of them are considerably older, and they are occasionally washed to be rid of the green mould, by which they get nearly obliterated, then dried and hung up again. Up to the present date they are fairly bright—brighter than many new prints of the present day. True, some have lost their half tones, and some the paper has actually dropped to pieces, and all look yellowish in the lights; but what picture, unless it was in oil, could stand such a test without deterioration? As to the discolouration of the paper, it would probably have become discoloured if it had not been subjected to any photographic treatment whatever. When photographs are mounted the protection afforded by a lithographed tint seems considerable in case there is anything deleterious in the mount itself, but plain or toned cards, so far as I have been able to judge, are little likely to cause fading; but a stout toned paper often made up into scrap albums has, I know, in some cases entirely spoiled the photographs mounted upon it.

To return to the printing. Undoubtedly the best results from most negatives are obtained in strong diffused light; there is more harmony and quality about them than when printed in direct sunshine; the strong direct light penetrates the thinner and more delicate parts of the image and over-prints before the denser parts are sufficiently done. The consequence is we have a flatter result and

a worse colour; on the other hand, a *very* slow light gives increase of contrast, and the probability is the proofs will be wanting in half tones if a negative of the same density is used in both cases.

The process of toning is considerably affected by the quality of the light in which the impressions are made. There are exceptional cases, in which the most powerful sunlight is necessary to penetrate the image, and even then the printing is but a tedious process. I need scarcely say such negatives would not be made by choice; still they have occasionally to be printed. A very thin negative, on the contrary, requires an exceedingly weak light in order to increase the contrast as much as possible, but at best of times the result is but indifferent, and I believe such prints are, of all, the least permanent; and as to getting a rich, warm colour, it is out of the question. Very thin negatives may be made to give better impressions by covering them during exposure with a piece of clear yellow glass and print in a stronger light. This plan improves the brightness of the print but makes the colour much colder and less pleasant. For plans and such-like line subjects the particular tint is less important than its brightness, and the method may be used with advantage. In the case of no yellow glass being at hand, ordinary white glass, coated with spirit varnish in which iodine has been dissolved, answers every purpose. The objection to coating the back of the negative at once is the danger incurred of getting the iodine varnish on to the film, which, it is needless to say, would give rise to trouble. Yellow paper does not answer the same purpose, nor will any screen that diffuses the light. It seems imperative to success that the light should pass direct through the negative to get the additional brilliancy. A yellow screen diffusing the light merely increases the time required for printing without strengthening the image in anything like the same proportion. Weak white and yellow lights have different effects, although both lengthen the time of printing; so one cannot be satisfactorily substituted for the other. Very much of the beauty of the colour of the print depends on the kind of light that reaches the paper through the negative. The greater freedom from yellowness, the more pleasant the colour of the print, although with some the removal of the yellowness would too much reduce the printing density, and intensification would have to be resorted to to make up the deficiency. I do not mean to infer that good prints cannot be made from yellow negatives, but that, if the density was correct, better would be made from colourless ones, and the advantage would be in colour. A weak yellow negative, slightly fogged, is of all the most impracticable, and I never yet saw a decent silver print obtained from such direct worth the paper it was on. Unfortunately there are many such in existence, and are a continual source of dissatisfaction both to the taker and the printer.

Everything being in the best working order, the depth of the printing should only require to be a little deeper than the finished work. If there is much reduction in toning and fixing, something or other is not as it should be, provided, of course, that the negative is right; any part of the process may be in fault, so may the paper itself. Supposing it is the paper, the remedy is obvious: get another sample. The toning bath may be out of order, or the fixing bath too strong, or the hyposulphite bad, or the prints may be left too long in either. With the majority of printers the fault is in the toning: the bath may be too strong or too new, or improperly made. Most ready sensitised papers work best with a weak, warm toning bath, but before they are immersed in it they should all be passed (after removing the bulk of the free silver) through a bath containing two or three ounces of pure carbonate of soda to the gallon of water, and washed again to remove the soda. One frequent source of bad prints is owing to the introduction of acid from the paper into the toning solutions. A very little acid or an infinitesimal quantity of hypo will spoil the best toning solution ever made. The soda treatment is almost imperative, or patchy, irregular toning will be sure to be the case. If only a few prints are being treated, persistent washing and soaking may remove most of the acid, and the toning may proceed without much difficulty, but a great improvement is effected by the alkaline application, so much so that it is best never to omit it.

As to the composition of the toning bath, almost any published formula will give good results, but one formula may suit a special sample of paper better than another. For my own part, I give the preference to a toning bath that will produce black tones, if required. Much more depends on the preparation of the paper than on the toning bath. As to the eventual colour, perhaps for those who only print a few prints now and then the old acetate bath is as good as any, as it will keep for a long time, and rather improves by keeping than otherwise, and there is very little danger of over-toning with it, and the colours given are pleasant ones. Other toning baths, made with carbonate of soda or lime, will not keep indefinitely, and are at their best soon after preparation. With strong negatives the carbonate of

soda bath gives especially rich purple blacks, but colour is so very much a matter of personal liking that it must be left to the operator. There are doubtless ready sensitised papers in the market that will not tone well, or even passably, with any formula, but if this undesirable quality proceeds from an initial fault in the preparation, or from too long keeping afterwards, it is impossible for outsiders to say: the fact remains. In order to have some guide to any source of failure, a known good sample of paper should be tried with any new lot. If all goes right, one may be satisfied with the paper, and must look at home for any fault that may afterwards occur; but if the guide piece remains good, and the new paper works badly, there is no trouble in localising the failure, and the paper must be changed as unsuitable. A good paper should possess the following characteristics:—Print quickly; tone easily; give a rich, bright impression, clear in the light and velvety in the shadows; fix with slight reduction in strength; be free from streaks or metallic spots; and not blister or tear readily.

The hyposulphite fixing bath is best made of a strength of one to five or six. A much weaker bath will fail to dissolve out the hyposulphite of silver formed; prolonged time in a weak bath is not equivalent to a shorter one in one of the strength above mentioned. The use of a too weak or exhausted hyposulphite bath is, I believe, the principal reason of the want of permanency attributed to silver prints. No matter how carefully every operation is performed, unless the print is properly fixed no reliance can be placed upon it. This bath should never be used quite cold, say less than 70°. It may be noticed, if cold water is used to dissolve the hyposulphite of soda, the temperature will be considerably lowered, and the more rapidly the solution is effected the colder it will be. Prints at once placed in this cold bath will in all probability be only partially fixed, though they may remain in the usual time. The temperature is, therefore, an important consideration. Finally, after fixing, the prints should be rapidly washed for a short time in frequent changes of water to remove all the loosely adherent hypo. They may then be completed by soaking for some hours in tepid water, squeezing and draining occasionally; many give a finishing bath of boiling water, which plan has nothing to be said against it, providing the paper does not become too soft and tender by the removal of the size. The prints may then be dried either on frames covered with calico, or between sheets of blotting paper.

EDWARD DENMORE.

HOW I PHOTOGRAPHED THE WORLD'S HIGHEST MOUNTAIN.

THE nearest point from Darjeeling which affords a peep of Mount Everest is Senechal, which is about 8000 feet high. Away to the north-west will be seen Everest, appearing in the distance of the size and shape of the point of an egg. This view is anything but imposing, as Everest is too far off, about eighty miles as the crow flies, and hidden from view by the Ghoompahar range. The best view of Everest is obtainable from Santakphu or Phalut, distance from Darjeeling about fifty-six miles, and 12,000 feet high. Mr. Cowell and myself started on this arduous expedition with a view of obtaining, if possible, a negative of Everest, the highest peak in the world, on the 10th November, 1886.

The weather was very unfavourable; we were enveloped in thick fog, and had occasionally a wetting. The first day we got as far as Tonglo, 10,074 feet high, and continued our journey the next morning. Five miles before reaching Santakphu, at a height of 11,000 feet, the drizzling rain changed into a snowstorm, and we were glad to reach the rest-house at Santakphu, 12,000 feet high, as the road got very slippery for the ponies. We had to stop here for the rest of the day, as the snow came down in earnest and continued all night. It was bitterly cold at this elevation; everything froze except the whisky, of which we had a good supply.

The weather very fortunately changed early next morning, and we had a glorious view of Kinchinjunga and Everest; the atmosphere was very clear, and made the peaks appear quite near. All trees were covered with snow, which glistened in the rising sun, making the landscape look like a fairy scene.

The camera was soon on the stand, and we took a few negatives of Kinchinjunga, and, after refreshing the inner man, we started for Phalut, from whence we expected to get a still better view of Everest. The road from here runs through that beautiful pine and rhododendron forest, which, in the beginning of April, is in one blaze of various colours.

The height of Phalut is 11,811 feet. We observed that the best time to photograph Everest was soon after sunrise, as a little later the broad shadow on the higher peak disappears and all is one mass of white. This fact proves that the centre and smaller peak, which is Everest, stands by itself many miles beyond the front range. It is said by some unknown big man that the distance between the front range and Everest is fifty miles.

Next morning we were ready long before sunrise, and after selecting a suitable place with regard to foreground, we waited till the sun gradually rose and lighted up the snowy peaks. Sunrise and sunset from any of these points is probably the finest sight in the world.

We exposed about eight plates of different makers.

The exposure we gave was between one and two seconds.

The lens used was one of the single combination of a 12 x 10 triple achromatic, which gave about thirty five inches focus. I found this lens very suitable for distant views, as it gives a large image with great depth of focus.

After returning to Darjeeling we developed our exposed plates, and the best results were obtained with Tailler & Clayton's isochromatic plates. The next best (but not to be compared with the former) were Wratten & Wainwright's make. The Britannia plates which we exposed proved a complete failure. Everest was not even visible, and the foreground dim and flat.

In conclusion, isochromatic plates are the best for distant objects such as Kanchenjunga or Everest, and give a very brilliant negative with true intensity in tint and colour, and are quite as rapid as the best plates in the market. The negative of Everest we have taken is the only one in existence.

—Journal of the Photographic Society of India.

THEODORE HOFFMANN.

A NEW CAMERA.

We have just examined a new camera containing several new features. It is made by Watson & Sons, and is intended for the Richmond Exhibition. It folds into a smaller compass, and is lighter and more portable than any other pattern we have yet seen. The back has reversing frame for vertical or horizontal pictures, and also swings in both directions, while by a novel arrangement it may, when required for use with a wide-angle lens, be pushed forward close to the front, so that there is no protruding baseboard to interfere with the angle of the lens. When the camera is open, the back automatically sets itself at right angles to the baseboard, from whence it may be swung as required. The front is of perfectly novel construction, giving a very great range of rise and fall, and fastened at the side by a ratchet instead of a loose front screw, which ratchet is automatically released when the camera is closed, and allows the front to go to the centre of the camera, when, as then happens, it is naturally drawn by the bellows, so obviating any difficulty in folding the camera.

The baseboard is fitted with a combined turntable and tripod head, of light, yet strong, construction, the design of which has been registered. The tripod stand is also quite new, there being three sliding joints, fixed by rack and ratchet, and entirely dispensing with screws or projections of any sort. The portability of the camera is remarkable in sizes as small as $\frac{1}{2}$ and $\frac{1}{4}$ plate, but when it comes to such sizes as 12 x 10 and 15 x 12, the saving in size is most apparent, the thickness of a 15 x 12 being scarcely more than an 8 $\frac{1}{2}$ x 6 $\frac{1}{2}$, and only about one-half the bulk of the lightest pattern cameras one usually sees.

THE SOLAR ECLIPSE.

The eclipse of the sun, which took place on Tuesday, was well observed from several parts of the line of totality in America. Many photographs have been secured.

At Anaheim no photographs were secured, but it is claimed that an intra-Mercurial planet was seen during the period of greatest obscuration.

At Lick Observatory the eclipse was successfully observed, and a number of photographs were taken.

At Letcham ten photographic views were secured during the period of totality, which lasted 1 min. 44 secs.

The party of observation at Bartlett Springs report that the corona was beautifully distinct, and that they saw remarkable changes in the length of the coronal lines. They obtained nine photographs of all contacts, studied the structure of the inner corona, and made even measures of light during totality.

Twenty five negatives were taken at Willows, California, to measure the brightness of the corona and its surroundings. Five of these were obtained to search for intra-Mercurial planets, and twenty to study the spectrum of the corona in order to determine its composition. These negatives will reach from the yellow rays to the extreme ultra violet.

The general illumination during the period of totality was found to be lighter than during the eclipses of 1878 and 1886. The corona was similar to those of 1868 and 1878, but showed much more detail than the latter, and was exceptionally fine, extending usually on one side to two solar diameters. A striking characteristic was two forked wings of light. The polar rays were well defined and considerably shorter.

At Clarendale the eclipse was observed with great accuracy, but shortly before totality some cirrus clouds passed over, all tinged with the most brilliant colours of the rainbow.

Venus appeared during the early stages of the eclipse, while Mercury and the other planets were plainly in view during every phase that was photographed.

To the observers at Healdsburg nineteen-twentieths of the sun's surface were obscured. The period of totality was eighty seconds. Venus, Mars, Jupiter, Mercury, and the principal fixed stars were visible. The corona appeared with long rays of light parallel to the sun's equator.

Professor Todd secured a number of fine photographs of the corona, showing rays extending ten or twelve degrees from the sun. Only rose-coloured protuberances were visible.

At Orland the period of totality was 110 secs. Venus and other stars were visible. Three successful photographs were taken.

At Winnemucca, Nevada, the observers were entirely successful. Accurate observations were made of the times of contact. One observer discovered a comet near the sun. No appreciable change of temperature was noticed at this station. Accurate observations were also made of the shadow bands. The corona was similar in general appearance to that of 1878. The streamers extended to a distance of from three to four diameters, and the red protuberances were strongly marked.

Our Editorial Table.

SELL'S DICTIONARY OF THE WORLD'S PRESS.

THIS wonderful two shillingworth, which has been brought up to date, contains, *inter alia*, practical hints as to the law relating to libels in newspapers, together with many other articles relating to journalism in every part of the world. It also contains sixty portraits of well-known journalists connected with the London and provincial press. Most truly is it a useful book of reference to all who are, or aspire to be, acquainted with matters associated with "the fourth estate"—the Press. Pp. 1452. Sell's Advertising Agency, 167-8, Fleet-street.

THE AMERICAN ANNUAL OF PHOTOGRAPHY AND PHOTOGRAPHIC TIMES ALMANAC FOR 1889.

Edited by C. W. CANFIELD.

THIS annual, though young in years, is growing rapidly in repute. The admirable style in which it is got up appeals at once to the lovers of fine bibliography, and this in book-making is of great worth at the present time. But it contains much that, apart from its fine typography and illustrations, is also of genuine merit and worthy of attention.

We shall take early occasion, as we have formerly done, to give our readers extracts from this admirable annual.

PHOTOGRAPHIC MOSAICS, 1889.

New York: E. L. WILSON.

THIS well-known American annual is now in its twenty-fifth year. It contains, in addition to a summary by the editor, a variety of articles by various American writers, one of whom (D. Bachrach, jun.) we are rather surprised to find is "down" on bromide prints.

PLAQUES FOR BROMIDE PRINTS AND NEGATIVES.

FROM Mr. W. Tylar, of Birmingham, we have received a specimen of his new *papier maché* plaques, on which to squeegee prints or negatives. It makes a good substitute for the more brittle ebonite, being strong, light, and well finished.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
January 7	Carlisle and County	Cathedral Hall, 57, Castle-st., Carlisle
" 8	Great Britain	5A, Pall Mall East.
" 8	Newcastle-on-Tyne & N. Counties	Mosley-st. Café, Newcastle-on-Tyne.
" 8	Derby	Sykes's Restaurant, Victoria-street.
" 8	Manchester Amateur	Manchester Athenæum.
" 8	Bolton Club	The Studio, Chancery-lane, Bolton.
" 8	Bradford	55, North Parade.
" 9	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 10	Birkenhead	Free Public Library, Hamilton-st.

" 10	London and Provincial	Masons Hall, Basinghall-street.
" 11	Ireland	Royal College of Science, Dublin.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, December 27, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. J. Briginshaw presided.

Mr. A. HADDON exhibited a negative of the interior of a laboratory in which a large portion of the plate was fogged, and he stated that this was due to the influence of the leather part of the dark slide upon the sensitive surface; the most brilliant objects represented in the fogged part of the plate exhibited reversed images. The plate had previously been in the slide a very long time; the exposure in the camera had been about one hour in dull weather. He did not think the effect to be due to atmospheric influences passing through the leather because there was no iridescence.

Mr. EDGAR CLIXTON thought that the plate had been fogged by a portion of it having been accidentally exposed momentarily to light.

Mr. HADDON said that about three months ago it had been stated that some one recommended a few drops of a solution of phosphorus in bisulphide of carbon dropped upon powdered chlorate of potash to give a flash light for photographic purposes; he would show the meeting how the plan worked. He first poured a little solution of phosphorus in bisulphide of carbon on blotting paper; in about a minute the liquid evaporated, leaving the phosphorus in such a finely divided state upon the paper that, as usual, it spontaneously caught fire from rapidity of oxidation; nevertheless it did not set fire to the blotting paper, but only charred it beneath the flame, the phosphoric acid produced by the combustion preventing the paper from catching fire. Next Mr. Haddon poured a few drops of the same highly dangerous liquid upon a few grains of finely powdered chlorate of potash; after the lapse of about a minute the mixture exploded with a loud report like that of a gun. Mr. Haddon expressed the opinion that the man who recommended using a flash light in that way for portraiture must be an idiot.

Mr. W. H. HARRISON said that if the flash gave light enough to photograph the sitter before he had time even to blink his eyes it ought to give better pictures than obtainable by any of the magnesium blow-through lamps in the market.

Mr. T. E. FRESHWATER said:—

I thought I would refer to the latest book on the optical lantern, just compiled by Mr. Hepworth, to see what information I could get from it on oil lamps for the lantern—the subject for this evening. Looking through the index, I find “Lamps, Newton, page 6;” on referring to page 6 I find the following: “The management of oil lanterns is so simple, really resolving itself into the necessity for keeping the burning wicks at a correct height and putting the pictures on the stage provided for them, that no more space need be given to the subject.” Well, that is dismissing the oil lanterns summarily, and I feel, with Mr. Hepworth, that there is not much more to say. One of the great secrets is cleanliness; care should be taken to light the lamp at least five minutes before use, so that the whole lamp may get thoroughly warm before being fully turned up; for when the oil gets hot it flows more readily, consequently its vapour is more rapidly thrown off. Care should be taken that the cottons are properly trimmed, not cut, as the raw edge of the cotton does not throw off that full volume of light which you get from the burnt edge of a cotton that has not been recently trimmed; all that is necessary is to take a piece of paper and rub off any charred part, taking care that none of it falls into the space between the cottons and, perhaps, stopping up the perforations. It is very important these perforations should be kept quite clean and open, so that the current of air passing through to the flame may in no way meet with interference. Much depends on extreme care in keeping the lamp clean both as to obtaining a good light and securing freedom from smell. The question of condensers and front lenses has been gone over so many times that it calls for no remarks now. There is nothing in this lantern which is new; I have only brought it at your request, so the best thing I can do is to light the lamp and show you how it works.

Mr. Freshwater then worked the lantern for about half an hour, projecting various pictures upon the screen, without the lamp giving either smoke or smell. He said that a good four-inch condenser would illuminate an ordinary slide better to the edges and corners than a half four and a half inch condenser.

Mr. HADDON remarked that one way of avoiding smell in subsequent operations was to carefully empty all paraffin from the lamp at the close of each exhibition, otherwise by capillary attraction it would continue to rise in the wick and afterwards run down on the outside of the lamp.

Mr. BRITISHMAN had found three-wick to work better than four-wick lamps, and to give as much light.

Mr. F. A. BRIDGE had had the same experience.

Mr. HARRISON remarked that in buying an optical lantern it was well to obtain a guarantee from the vendor that the back lens of the projection combination was large enough to take in the whole of the cone of rays coming through the picture, otherwise there would be loss of light from a too common defect in lanterns.

Mr. HADDON asked why the parallel wick could not be placed slightly diagonally to the axis of the optical system, so as to throw no dark vertical line or lines across the luminous disc on the screen.

Mr. FRESHWATER replied that the plan had been tried and there was a loss of light.

Mr. CLIXTON had tried it with a two-wick lamp, and found that there was a loss of light.

Mr. HADDON could not see why such should be the case, flame being transparent to light.

Mr. FRESHWATER said that a stone found near Nottingham was found to burn into the best lime for lanterns, but the lime cylinders made of it are at present badly turned and badly drilled.

Mr. BRIDGE had found that the aforesaid lime from a Nottingham stone was the best in the market.

AMATEUR PHOTOGRAPHIC ASSOCIATION.

A COUNCIL meeting of this Society was held Friday, December 28, at 12, Old Bond-street.—The Right Hon. The Lord de Bosc in the chair.

The minutes of the last meeting having been read and confirmed the following members were elected:—Messrs E. A. Tower, S. A. Garnett, and Albert Norman.

The SECRETARY then laid before the meeting the prizes which had been awarded at the annual meeting, which were as follows:—Mr. B. O. Milne (the first prize), a large silver goblet; Mr. F. S. Senwale, a silver goblet; Mrs. Hobson, a silver goblet; Mr. W. Galdum, a silver goblet; Mr. R. Leventhorpe, a handsome landscape album; Mr. W. S. Hobson, a silver goblet; M. Maurice de Delys, a handsome portrait album; Dr. Drew, a small silver goblet; Mr.

R. Murray, a handsome landscape album; and Mr. F. Gowan, a handsome portrait album.

These prizes were approved by the Council, and the Secretary was directed to forward them to the members to whom they had been awarded.

The SECRETARY was directed to inform the members of the following resolutions which were proposed by the Earl of Rosse and passed at the previous meeting:—1. That the last day for receiving negatives, so that they shall be guaranteed an entrance into the annual competition, shall be May 1. 2. That negatives received after that date, and until the meeting of the Referees, shall as far as possible be entered, but they shall not be guaranteed entrance unless they be accompanied by a print from each. 3. That the unpunctuality of members in sending in negatives shall not be considered a reason for the postponement of the meeting for the award of the prizes.

CAMERA CLUB.

On Thursday, December 27, the slides sent in by members for the exchange with the New York and other American Photographic Societies were exhibited. In all about two hundred were shown, and from these one hundred will be selected to send to the United States. Among those contributing were Messrs. Gale, Conway, Wainwright, Beasley, Greene, Howlett, Davison, Ferrero, Carnell, Sturme, Shipton, Stroth, Elder, Robertson. After the exhibition, a short discussion took place on the marking of lantern slides.

On Thursday, January 10, another lantern show will take place at the Club.

WEST LONDON PHOTOGRAPHIC SOCIETY.

The inaugural meeting of this Society was held at Addison Hall on Friday, December 28, when a large number of ladies and gentlemen attended to hear the inaugural address from the President.

After the disposal of the formal business, the PRESIDENT (Mr. William England), in the course of his address, said a photographic society for West London was now actually in existence, but its success in the future would depend to a great extent on the hearty co-operation of every member. It was not to be forgotten that many societies were already in existence, and some of them had had a long start of the new society, still he trusted it would never, after all the energy and trouble which had been expended, be said that the West London infant would not grow into manhood. It had been said in some quarters that another London society was not required, but that was an opinion which he certainly could not endorse. Central and other parts of London were, undoubtedly, already provided for, but surely the western district, which probably contained more photographers, amateur and professional, and persons interested in art culture than any other portion of the metropolis, should be represented by a photographic society of its own. He reminded those present that ladies were eligible for membership, and probably in West London there were many lady amateurs who would fully appreciate the advantages to be derived from becoming members of such a society; he, therefore, trusted that a large number of ladies would join and honour the Society by their presence at its meetings. It was a fact not to be overlooked that photographers of the present time possessed great advantages over those who practised the art in its earlier days. At the time to which he referred there were no photographic periodicals to appeal to for help and guidance out of a difficulty, and photographic societies, of which there were now upwards of eighty established in Great Britain, were things unknown. The President, in concluding his address, gave an interesting résumé of the Daguerreotype process, and, to illustrate his remarks, handed round for the inspection of the audience some valuable early specimens of the process, including a portrait of Daguerre, a portrait of himself, a copy of a picture, and a fine instantaneous study.

After a vote of thanks had been accorded to the Chairman for his address, Mr. HARRISON LOW said that the President, in the course of his remarks, mentioned that the real work of the Society had only just begun; but, with all respect, he ventured to disagree with him upon the point. They should not lose sight of the fact that they owed a debt of gratitude to four gentlemen—Messrs. Blackmore, March, Bennett, and Hodges, who were really the originators of the idea of forming a photographic society for West London, and that it was they who had undertaken all the trouble incident to and inseparable from the work of promoting such a society as the present. Bearing this fact in mind, he thought it only fair to the gentlemen he had named that the meeting should mark its sense of its appreciation of their services by according them a hearty vote of thanks for the expense and trouble to which they had been put.

The motion having been seconded by Mr. Whiting and carried unanimously, Mr. HODGES returned thanks on behalf of himself and those who had been associated with him in forming the Society, and said that the future success of the Society would rest in a great measure with each individual member and not alone with the executive; they might have the most capable President and the most zealous officers, but such a desirable condition of things would not make the Society a success without the hearty co-operation of all the members. There was also another matter which he wished to impress upon them, and that was the necessity of regular attendance at meetings on the part of members. They must bear in mind that they were now an existing society, and as such were open to public criticism, and it was unnecessary to remind them that photographic criticism was very keen.

The optical lantern was then called into requisition, and a number of slides, the work of members, were exhibited, including a fine series of Continental and instantaneous views by the President. Mr. Whiting contributed a series of views in Ely and Canterbury produced by the wet collodion process. Messrs. Varlen, March, Bennett, and Hodges, also contributed views.

The CHAIRMAN announced that Mr. G. F. Blackmore would read a paper entitled *Notes on Ferron Oxalate Development* on January 11, and that Mr. Hodges would give an account of a tour in North Wales, with lantern illustrations, on January 28.

A vote of thanks to the President for presiding terminated the proceedings.

The next meeting of the Society will be held at the Addison Hall on Friday, January 11, at eight o'clock.

HALIFAX PHOTOGRAPHIC CLUB.

The monthly meeting of the above Club was held in the Mechanics' Hall on Thursday evening last.

Mr. R. Kemtani read a paper, *To the Alps with a camera*.

Mr. Alston Palmer exhibited a large number of views by the aid of the limelight, being the joint production of himself and the lecturer. The pictures were very interesting, being chiefly drop-shutter views taken in the various cities visited and from the steamboats as our travellers passed up the Rhine.

EDINBURGH PHOTOGRAPHIC SOCIETY.

At the meeting held on December 5, 1888, the President in the chair, nine new members were elected, namely, Messrs. A. J. Rannerman, James Burns, Robert Grieco, James Macadam, Andrew L. Smith, J. Steel, Alex. Walker, Fred. Wank, and J. H. Young. Eighteen gentlemen were nominated for election at the January meeting.

Mr. Robert T. Salmon then read a paper entitled *The Photographic Harvest of 1888*, in which he pointed out the rapidity with which applied photography has recently advanced. A vote of thanks was accorded to Mr. Salmon.

Mr. A. A. Inglis presented the Society with the Parker's sky shade which Mr. Macbeth, R.N.A., had brought before the notice of the Society some years previously. Mr. G. G. Mitchell, in the absence of Mr. Inglis, exhibited the method in which the sky shade worked, and handed it over to the Curator.

The members then proceeded to inspect the specimens of members' work hung around the room. The quantity of exhibits showed a slight falling off as compared with that of last year, this decrease being generally attributed to the general unamiable weather characteristic of the past summer. One noticeable feature to the exhibition was the growing popularity of developed bromide prints, as evidenced by their comparatively large number.

The first "popular evening" will be held in Queen-street Hall on Thursday, January 17, 1889, when Mr. David McGibbon, F.S.A.Scot., will lecture upon *The Cathedral Structures of Scotland*, comparing period with period, and especially pointing out the characteristic features of each.

It is intended that the second popular evening—devoted to the exhibition of members' work only—shall take place on Thursday, February 21, when a musical programme will form a special feature in the proceedings. Members are particularly requested to send in their slides to Mr. William Forgan, 13A, Friar's-place, or to Mr. J. M. Turnbull, 6, Rose-street, on or before Monday, February 12, and to see that each picture is legibly titled. The observance of these precautions will enable the Council to do their work more efficiently, and will tend to the prevention of mistakes.

ALLAHABAD CAMERA CLUB.

The first general meeting of the above Club was held at 9, Albert-road, at six p.m., on December 11. President, the Hon. Mr. Justice Straight. The meeting opened at a quarter past six p.m.

After the ordinary business of the Club had been disposed of, it was decided to form a class of instruction, commencing with the A B C of photography, under the able supervision of the Secretary. Classes to be held weekly, open to all members. Camera, chemicals, and dark room, free of charge, being supplied at the cost of the Club.

Colonel Brown Constable then exhibited a short series of lantern transparencies prepared in various manners, and showing practically the various results caused by the various developers used.

Afterwards a discussion was held on the Brown-Constable changing bag, and a practical proof of its excellence was given by its inventor and patentee (whose name it bears) changing and recharging with plates three double dark slides for 3½ x 6½ plates. This work was done, though under difficulties, in ten minutes.

After a little general discussion the meeting closed.

The next regular meeting of the Club will be held on Tuesday, January 8, 1889.

All communications to be addressed, Mr. A. Wingrave, Secretary, Allahabad Camera Club, 9, Albert-road, Allahabad.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

A STATED meeting of the Society was held Wednesday evening, December 5, 1888.—The President, Mr. Frederic Graff, in the chair.

Nominations for officers and standing committees for 1889 were made.

A paper was read by Mr. HENRY HARRISON SPYLER on *The Largest Camera in the World*, being a description, particularly in its application to astronomical photography, of the Lick telescope.

Mr. Spyler also presented to the Society, on behalf of Messrs. Warner & Swasey, of Cincinnati, the builders of the telescope, three fine photographs showing the instrument as mounted in the observatory.

Dr. CHARLES M. MITCHELL gave an interesting account of a photographic trip taken during the last summer in the White Mountain region of New Hampshire. A large number of excellent slides were shown as the result of the trip.

Mr. CARBUTT showed some transparencies made on his new flexible negative films, which were of great beauty. They were mounted between two sheets of plain glass, no ground glass being required. An excellent portrait negative made on a film by Mr. Gutekunst was also shown. As a convenient method of using the films in ordinary holders, Mr. Carbitt showed some carriers made from sheets of ferrotype plate, the edges being bent over in such a manner that the films could be readily inserted and firmly held, so that the carriers could be placed in position in the holder. He called attention to the absence of halation when films were used, the smallest twigs and branches of trees being perfectly sharp. Negatives taken in the building of the American Institute Fair, in New York, a portion of the skylight being included in the view, were

entirely free from halation when taken on the films, the decided reverse being the case when glass was used.

In reply to a question by Mr. Burroughs, it was stated that the tendency to curl in drying could be obviated by first placing the film for three or five minutes in a mixture of water, thirty ounces, and glycerine, one ounce.

RECENTLY ELECTED OFFICERS OF SOCIETIES.

AUCKLAND CAMERA CLUB.—Meetings are held on the second Thursday in each month. Annual Meeting, second Thursday in November. *President*: S. C. Brown.—*Hon. Secretary and Treasurer*: A. G. Tibbitt.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.—*President*: Richard Hill Norris, M.D.—*Vice-Presidents*: W. J. Harrison, F.G.S., E. H. Jaques, B. Karleese.—*Council*: F. Barnett, J. J. Button, J. C. Fowler, F. Hoskins, S. G. Mason, E. C. Middleton, A. Pumphrey, G. A. Thomason.—*Librarian*: S. T. Holliday.—*Treasurer*: T. Taylor.—*Hon. Secretaries*: J. H. Piekard, 361, Moseley-road, and William Rooke, Ascot-road, Moseley.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.—*President*: T. Mansel Franken.—*Vice-Presidents*: J. W. Insole, Jonas Watson, J.P., S. W. Allen, M.I.M.E., Alexander Kellar.—*Hon. Treasurer*: W. Foster.—*Hon. Secretaries*: G. H. Bedford and G. H. Wills, jun.—C. F. Gooch, George Shepton, H. L. Bridger, Rev. W. Whiteside, W. Windsor, T. H. Faulks, and E. H. Bruton, were added to the Council.

CINCINNATI CAMERA CLUB.—*President*: George Bullock.—*Vice-President*: George McLaughlin.—*Librarian*: Archibald I. Carson.—*Treasurer*: T. H. Kelley.—*Secretary*: Emery H. Barton, 171, Race-street, Cincinnati, Ohio, U.S.A.

HEREFORD CITY AND COUNTY AMATEUR PHOTOGRAPHIC SOCIETY.—Established 1888. Meetings, first Thursday in each month at half-past Seven. *President*: James Rankin, M.P.—*Vice-Presidents*: Thomas Blake and Rev. W. Bowell, M.A.—*Council*: C. B. Beddoe, Edgar Morris, M.R.C.S., Alfred Watkins, Will Parker, James Godwin, A. H. Smith, J. Runkin, jun., E. G. Davies, Robert Clarke, W. Wilson.—*Hon. Treasurer*: B. Culwick.—*Hon. Secretary*: John Parker, A.M.I.C.E., Mansion House, Hereford.

HUDDERSFIELD PHOTOGRAPHIC SOCIETY.—Meetings are held on the first and third Wednesdays in every month at the Society's Rooms, Byram-buildings, Station-street, Huddersfield, at Eight o'clock. The dark rooms, enlarging, and reading rooms, are open for the accommodation of members daily. *President*: Surgeon-Major Foster.—*Vice-Presidents*: John Ed. Shaw and T. K. Mellor.—*Committee*: H. G. Brierly, A. Clark, B. Crook, T. Fitton, H. Haigh, F. W. Mills, G. B. Nahder, H. Young.—*Curator*: W. H. Charlesworth.—*Hon. Secretary and Treasurer*: H. M. Smith, 15, St. John's-road, Huddersfield.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.—*President*: A. W. Beer.—*Vice-Presidents*: H. N. Atkins and H. Lupton.—*Council*: R. R. Gibbs, G. A. Kenyon, M.D., P. H. Phillips, E. Twigge, P. Lange, D. Lewis, W. P. Riley, G. H. Rutter, R. Crowe, E. Roberts, B. J. Sayee, W. Tomkinson.—*Librarian*: W. Hughes.—*Auditor*: W. H. Kirkby.—*Hon. Treasurer*: Joseph Farr.—*Hon. Secretary*: Walter A. Watts, M.A., Highfield-road, Appleton, Widnes.

PACIFIC COAST AMATEUR PHOTOGRAPHIC ASSOCIATION.—Established February 19, 1883. Regular Meetings, once a month, held upon the first Thursday after the first Monday in each month, at Eight o'clock p.m., at 605, Merchant-street. Annual Meeting to celebrate anniversary. Exhibitions annually. *President*: A. J. Treat.—*Vice-President*: George W. Reed.—*Executive Committee*: W. H. Lowden, Dr. E. W. Ruyon, Dr. S. C. Passavant.—*Treasurer and Secretary*: James H. Johnson, 414, Buchanan-street, San Francisco, California, U.S.A.

Correspondence.

Correspondents should never write on both sides of the paper.

PROPOSED PHOTOGRAPHERS' DEFENCE UNION.

To the Editor.

SIR,—At no previous period in the history of photography has there been such need for a co-operation of professional photographers as at the present time.

The decision of Mr. Justice North, *in re Pollard versus Photographic Company*, threatens to still further seriously interfere with the already much handicapped profession; unless a decisive step is unhesitatingly taken, and generously supported by professional photographers, any one of our brethren may be proceeded against at any moment by some spitefully inclined person for simply exposing a specimen in his show-case, or supplying a re-order to the wrong member of the family. The case cited above will furnish a dangerous precedent if it is suffered to become law, therefore no stone should be left unturned to prevent this.

If the facts of the case, as revealed by the proceedings, formed the only basis, there would, of course, be an end of the matter, as no respectable photographer would part with any copies otherwise than to the sitter or relatives, or with the former's permission, nor do I believe that he would hesitate one moment to remove any specimen from his window (or would never exhibit at all) after a request to that effect, but the case presents a slightly different aspect.

The defendant, with whom I am acquainted, belongs to the first rank of the photographic profession, and is an artist of no mean order, and it must be a matter of regret that he allowed the case to be conducted by affidavits instead of witnesses being heard orally, for or against, and, further—

more, I must say that in my opinion it was a mistake on the part of the defendant's counsel to contend that the photographer could make what use he pleased of a negative. However, as that cannot now be remedied, I trust that an appeal may reverse the decision when the case may be clearly stated as follows:—

The plaintiff, a solicitor, having paid an account he owed to the defendant, ten days afterwards brought this action. (In case of my readers misconstruing my words, I wish it to be distinctly understood that I do not mean to say that this action was brought out of spite; on the contrary, I firmly believe that a gentleman of such high standing as a solicitor could not possibly be capable of such meanness. Even if [some might think it a remarkable coincidence, I am quite sure that such coincidences do occur in every-day life having no particular meaning attached to them). An exceedingly good and pleasing photograph of the plaintiff's wife was inserted into one of the usual Christmas designs (as is the custom of trade from its infancy) and exposed in the shop window for a considerable time, during which the plaintiff's wife frequented the defendant's shop several times, and although knowing it to be there never objected to it.

Then the plaintiff's clerk purchased one on the detective system, having previously and repeatedly been asked whether he had the lady's permission. The action was tried, with the result known. It is easy to imagine the consequences if the decision is permitted to stand. First of all every photographer, apart from being liable to be prosecuted from an unknown enemy, will probably have to part with a valuable negative to the amateur friend of the family who will furnish all after copies. Secondly, if he insists in retaining the negative, the material of which clearly belongs to the photographer, the necessary permission to supply after copies will lead to no end of complication, as, for an instance, a group of twenty having been photographed, any one member's consent in writing will be required to supply the other with a copy, and it is truly appalling to contemplate what formalities will be requisite in the case of an after order, supposing some of the company to have emigrated to the Cape of Good Hope or elsewhere; or it may happen that an application for permission to sell photographs to members of the family cannot be entertained until a list of those relatives, who may or may not be supplied, has been prepared. A gentleman, engaged to be married, accompanies his intended bride, and actually pays for her photograph. At an impending breach of promise action the gentleman orders some more copies, and so may drag the unsuspecting photographer into his meshes. Examples like these might be drawn *ad infinitum*, and it would require an extra clerk to guard against the law; therefore it is clear something must be done.

The leader in your last issue should alone suffice to bring about a protection society. If we do not band together now, such gross omission will surely become a standing reproach to us. The defendant in the case of Pollard versus Photographic Company is inclined to pay the costs in the action, being afraid of incurring the risk of an unsuccessful appeal.

The chances are very much on the defendant's side if the case were carried into that Court. All previous decisions have been in favour of the profession, and it has always been understood by photographers that the copyright is vested in the operator, and not in the sitter as pronounced by the judge.

In view of the great and acknowledged interest you, Mr. Editor, take in photographers, I ask you to lend your esteemed and valuable assistance to this cause, so that a society may at once be formed, or an appeal fund be started, to which I am happy to contribute 2l. 2s.

No time must be lost, as the term within which an appeal may be lodged expires in less than a fortnight, therefore permit me, through your widely-circulated journal, to invite the brethren of the craft to forward their names for membership immediately, whereupon an early meeting can be arranged, and the subscription paid, and other necessary formalities can be settled. Let it be remembered that this important matter concerns every individual member of our noble profession, and though it only affects a provincial colleague to-day it is not at all unlikely that it may be our turn to-morrow.

As experience teaches that for the want of an organised beginning many good schemes fall through, I venture (even at the risk of appearing over officious) to take it upon myself, if necessary, to act as secretary *pro tem.*, until the ship is successfully launched within smooth waters, when I shall conceive it my duty to deliver it up to the guidance of abler hands, who I sincerely trust may steer it in grand style through the strongest currents.

That it may be quickly and powerfully manned and accomplish its grand object, is the earnest wish of—Yours, &c., J. HUKAR.

OWNERSHIP OF THE NEGATIVE.

To the Editor.

SIR,—I see two judges have decided that the copyright of the negative belongs to the sitter. How would it be if a picture was taken of a person with a hand camera, the person photographed being quite unconscious that he was being done? In this case, also, it is clear, if the judges are right, that the negative belongs to the sitter. A landscape photographer must, therefore, be cautious, as if he puts a figure in the foreground the negative will belong to the figure, and what would happen if he had

several figures—say a street scene—I am at a loss to imagine. The whole of those included would have a "joint estate" in the result. They would be "co-owners." This would lead to an exceedingly perplexing state of affairs. Any one in the crowd could prevent the publication.—I am, yours, &c., F. J. Q.

Camera Club, 21, Bedford-street, W.C., December 29, 1888.

PSYCHIC PHOTOGRAPHY.

To the Editor.

SIR,—I am pleased to be able to send you the result of your criticism in THE BRITISH JOURNAL OF PHOTOGRAPHY, September 14, 1888, in reference to the apparent double exposure in the spirit photographs you saw. It appears to have been due to a phosphorescent halo which surrounds the spirit, and which is capable of penetrating to the plate in the camera when the room is full of light-coloured magnetism; consequently, when the magnesium is lighted, it stamps the sitters in the body on the plate as well, but whether this is necessary to impress the spirit also was the point in question.

The plate, a print of which I send you, was taken under the following circumstances, the focussed sitters being myself and a lady friend, very incredulous, but sufficiently anxious for knowledge to keep her mind calm and in a receptive condition. She is a frequent visitor here, and had frequently expressed a wish to go upstairs when we were sitting; she has now been sitting regularly several weeks, and every suspicion she had has vanished.

Among the correspondents my letters in your JOURNAL have brought me is a lady from Belfast. She was most anxious to come to see me and bring her son, who was an amateur photographer, to try to get some spirit photographs with me, for he could not believe that they were genuine because he can imitate them. As is my custom, and has been all my life, in all matters outside my own knowledge, "I inquired of the Lord," and received this audible reply: "Yes; you may invite the lady, and make her up a bed in the room you operate in. We have consulted with the spirits in her surroundings, and we will try to bring one forward; but as we wish you to make these experiments known to the world without coming in rude personal contact with sceptics who won't believe even the evidence of their own eyes, and who we know argue to have their own way, not to gain information, we would like you to suggest, when you write, that her son should try himself once per week for spirit photography until he succeeds, and in the meantime read what the leading minds have written on this subject." Thus encouraged, I invited her. She came, but a telegram summoning her immediate return home reached here before her arrival late on Monday evening; being tired out she went to bed, and proceeded on her homeward tour early the next morning, without the desired experiment in psychic photography. Now for the sequel.

On Tuesday evening (as is usual when convenient) I exposed three plates, one of which was developed without lighting any taper, or, in plain words, exposed in total darkness, quite black, the fire being screened and draped heavily. . . . When the plate was developed there were on it six distinct faces, and many indistinct ones. I printed it, and as none of the spirits were known to me in life, nor to my two friends who were present, I forwarded a print to the Irish lady's address, asking if she recognised them, feeling certain that my spirit friends would keep their promise, and complete their part of the agreement, though circumstances prevented me fully keeping mine. Instead of answering my question she wrote asking me to forward the negative, and if I would pay carriage she would return it. . . . But I considered my question merited an answer. I therefore wrote reminding her that she had not answered my question, that I was pleased to show the plates to any one, that I had three or four callers for this purpose most days (many of whom refused to give names, even after they have seen them and are satisfied), but that I did not feel disposed to part with them, even for a day, unless to relatives of the spirit shown, then I would willingly give up the plate altogether, provided they were willing to give a substantial donation to the Spiritual Evidence Conference, of which I am a member. The answer to this contained these cautious words: "I thought I recognised the spirit; I showed it to my daughter, too. My niece said it looked like me." Of course, if it were the lady herself, I must have had a portrait of her, which I had not, nor any like her, or she must have been dressed up and sat for it, which was not the case. But, supposing this was so, how about the other four forms, one of which is unmistakably an Irish face. Two heads are close together as mother and son, and the fifth an old lady smiling down upon the centre figure. Is it possible for these to be produced in miniature without separate focusing? In the meantime I send you the three negatives taken that evening, two with light and one without light, which kindly return in a few days. I feel that you are honestly interested in the subject, and are willing to investigate it if you can satisfy yourself of the genuineness of the phenomena. The chief plate has accidentally been damaged in the corner; it is the one developed without light. The lady's name is —. The details are intended for the consideration of those who every week confess, "I believe in the communion of saints," and yet superciliously resent and scoff at every attempt the saints make to establish such a communion as so much time lost in their chase after money. Angels are men continuing the life they commenced on earth;

and just in the same proportion as our relations and neighbours will not intrude their company upon us when they see they are not welcome, will this sensitive delicacy be increased, as all their other faculties are intensified by life in the spirit world. "He that hath friends must show himself friendly" applies as much to man's communion with angels as with men. A closer and more frequent communion between the spirit and the material world would have more power to check sin than all the sermons ever preached. I do not believe it possible for any person to take the photographs of spirits unless there be a sympathetic confidence existing between the operator and the spirit world. If the communion be an audible and a conscious one so much the better for results, but this is not so necessary as sympathy, contentment, and patience with, and confidence in, their efforts to fall in harmony with and impress the friends in the body who are operating for spirit photographs how to improve conditions.

Your criticism on the negative will oblige. I am, yours, &c.,
S. A. POWER.

Ladlow's College, 93, Ashford row, Birmingham, December 28, 1888.

P.S.—Of the two friends who were present when the three plates were exposed, one is the sister of the spirit pupil you were shown in Birmingham—a constant visitor here, though opposed to my views on the subject, and, though she has every confidence in me, thought I was the subject of a joke. During the last dozen sittings she has sat in the room, witnessing and examining every movement. She finds all her theories have to give way, because they will not dovetail with the facts as she witnesses them. (I enclose her name and address, but not for publication.) The third person present taught me photography indeed, still teaches me, for as you see there is much room for improvement.

[In the first place we must confess to having deleted portions of our correspondent's letter, which we thought did not bear directly on the subject of spirit or psychic photography. Hence, if there be any jerkiness in the style, we, not Miss Power, must be held responsible. One, at least, of the names she gives us is not unknown to us, and we quite admit honestly and truthful endeavour as regards research.

Concerning the negatives which accompany the foregoing letter, we shall not hazard any opinion, but shall very soon arrange to send Miss Power a binocular camera with which to institute a few more experiments. If with it she obtains any spiritualistic or psychic (call it what you will) phenomena and send us the negatives, then we shall feel we stand on stronger ground than when mere monocular impressions are concerned.—Etc.]

To the Editor.

SIR,—At the time that I am writing there are reaching me numbers of *The Harmonic Journal of Photography* in which there is much correspondence on the subject of *Psychic Photography*—a subject that, under one name or another, is continually cropping up. I imagine that the subject will have been pretty well threshed out before this reaches London, and I certainly hope that the discussion will have stopped, for the result of it is sure to be only one. No conclusion will be come to whilst those on both sides of the argument will display the most lamentable credulity, those on the one side allowing themselves to be taken in with what is, at times at any rate, palpable trickery, or allowing their preconceived notions to blind them to evident explanations of the phenomena that are observed, whilst those on the other exhibit the far worse credulity involved in the assumption that there are no forces possible but those that have been scientifically investigated, no senses possible but the five or so that have already been fully developed, and that, therefore, all that is commonly called "preternatural" or "supernatural" is impossible. A denial of the possibility of the so-called "supernatural" is always the result of the very shallowest scientific knowledge, and commonly gives way before a broader knowledge, at the same time that it comes to be recognised that "supernatural" is not the proper term to use. Looked at from one point of view all phenomena whatever are supernatural. We can explain no one of them even in the smallest degree. All our so-called "explanations" are merely statements of one phenomenon in terms of others. On the other hand, if we are ever able fully to investigate and to classify the phenomena now termed "supernatural," we will certainly find that order in their sequence which we usually, but wrongly, express by saying that the phenomena are "subject to natural laws." Nothing in the world is "subject to natural laws;" and "natural laws" being nothing but an expression of certain sequences which have been observed to take place with such unfailing regularity that we conclude, reasoning by analogy, that they hold in regions where we have not investigated, and that they will continue indefinitely.

It is not, however, to write an essay on the possible existence of the supernatural that I sat down, but to tell of a little event in photography that came within my own knowledge a short time ago, and that, at first, seemed so extraordinary that it appeared as if it might be classed amongst the things generally spoken of as "supernatural." Here is an exact account of the event.

A friend of mine, a very enthusiastic photographer in these parts, came to me the other day with a tale of the most startling kind. He had opened a new box of a brand of dry plates made in this country, and had exposed some of them. On going to develop them he was rather surprised that no image appeared for a long time—"rather" surprised I say

advisedly. He was working on a not very familiar subject, and admitted that possibly he had very much under exposed. He was, however, far more than "rather" surprised when at last an image appeared on the plate, but one of a view entirely different from that on which the exposure had been made. In three cases such images were got, and in one case the image was of remarkable clearness. The last-mentioned plate was brought to me, and then I saw that it was distinctly and unmistakably a transparent positive of the interior of a foreign house. Not only that, but the house and room were before long recognised. This was, naturally, not a very difficult thing in a place where there are but few European houses, and in the case of a photograph that showed some very uncommon "curios" on one of the tables. And now the mystery reaches its height. So far as it is possible to prove negatives (I do not use the word in its photographic sense here) it was proved, not only that none of the plates that gave a picture of a certain room in a certain house had ever been in that house, but, further, that no photographic apparatus of any kind had been brought within the doors of the house since a time considerably before that at which the plates that gave the mysterious images had been manufactured.

And here comes the "moral," if there is one. All the statements that I have given above were considered by all concerned to be fully proved. Suppose now that some one had wished to establish what may, perhaps, be given the name of "telepathic photography," and it would be pure Philistinism to deny the possibility of such, here would have been a most undoubted and undeniable case.

It is generally mere foolishness to deny the possibility of anything, but when we get beyond the beaten track it is necessary to exert ten times the usual care, lest we come too quickly to conclusions. The case in point is a good example. Our "supernatural" photograph was to be most completely explained, or, to be consistent with what I said at the beginning, was to be stated in terms of phenomena quite common and almost well known. The photograph was, after a time, recognised as a transparent positive of a part of a negative made months ago by a certain professional photographer. This discovery led to further investigation, and it was found that the supply of imported glass had run short in Tokio some month or two before the plates that gave the strange images had been made, and that the plate makers had bought up all the old glass they could get hold of, the particular negative just mentioned being amongst the lot. This brings our explanation down to a very simple matter. It is, indeed, merely a repetition of the old, old manner of producing spirit photographs, only that it was done quite accidentally.

There is, however, much that is interesting in this matter from a purely photographic point of view. In the first place, this is, I believe, the first record of the appearance, in the case of dry plates, of a phenomenon which was well-enough known in the case of wet plates. Then there is the further curious fact that the image was a *positive*, not a *negative*, as one would have expected had the glass retained any form of latent image. Further, there is the curious fact that the image appeared in the case of only three out of several thousand plates that were made from old glass. One theory is that the glass absorbed a certain amount of light, in the way in which sulphide of calcium absorbs light, and that it gave off this light to the plates. It will be observed that, if it be assumed that the plates were placed in a pile, in a brilliant light, with the film side of the particular negative that gave the image upwards—an assumption by no means extreme—the plate might absorb light in such a form as to give a positive image, if it were coated with emulsion and gave off some of its light after it was coated. On the other hand, the manner in which the plates were treated—as reported to me—makes it somewhat difficult to entertain this explanation. They were steeped for ten days in acid—one part hydrochloric acid to twenty parts water, were then washed in hot water, were further scrubbed with the vegetable sponges that prove so useful in this country under a stream of cold water, were placed for half an hour in a weak solution of chrome alum to prevent frilling (A. L. Henderson), and finally were rinsed in cold water and were dried. It is almost impossible to suppose that the absorbed light remained to such an extent in the plate through all these operations as to be able to produce an image on a gelatine emulsion. On the other hand, the fact must be borne in mind that a luminous surface—luminous from having absorbed light—will, upon the application of heat, after it has apparently given off all the heat that it has absorbed, sometimes give off a residuum under the influence of heat. It is just conceivable that such a residuum was given off from the glass when the hot emulsion was poured over it.

The theory that I give may be right or wrong—probably it is wrong; but I consider that I have established, or rather that the facts that I have described have established, one most practical point, namely, that it is not safe, even in the case of gelatine emulsion, to use glass a second time. I do not think that glass is at all extensively used a second time in coating with emulsion, for the reason that it barely pays to clean it, otherwise I should expect a vote of thanks from the glass makers.

Imperial University, Tokio, Japan.

W. K. BURTON.

DEFECTIVE SLIDES—DEVELOPERS.

To the Editor.

SIR,—With reference to the query put by "M. H. A." in your issue of November 9, I write to say that I have had great trouble since coming

to the sea coast with double backs, the hinges of which are made of leather. My experience, however, is the converse of "M. H. A.," for whereas he complains of a band of fog, I always had, not fog, but a band paler than the rest of the negative. This bleaching I attribute to the action of the sea air on the silver bromide. As a remedy I tried wax, then shellac varnish, but they proved ineffectual. I then tried Bates' black varnish, which so far has proved satisfactory.

As I am writing to you I may mention that I have found anhydrous sulphite of soda in the alkaline part of Beach's developer (when used in the proportion of half the quantity, by weight, of the equivalent amount of ordinary sulphite of soda) most unsatisfactory. It produces severe frilling on plates which develop without a trace of frilling when ordinary sulphite of soda is used; and I believe, also, that it leads to fog.—I am, yours, &c.,

T. M. HORSFALL.

Madras, December 2, 1888.

HYDROQUINONE AS A DEVELOPER FOR COLLODION EMULSION.

To the Editor.

SIR,—I trust you will not think I am wasting your valuable space by giving a short experience of the above as a developer for collodion emulsion dry plates. I determined to try the Beechey plates for making lantern slides. I accordingly made up the developer given with each packet of plates, which consists of pyro in alcohol and carbonate of ammonia as alkali. I exposed a plate for about one minute and a quarter, at a distance of two feet six inches, under what is rather vaguely described as a negative of "average density." I then flowed the developer over it continually for over three minutes, but no signs of an image up to that time. Getting somewhat impatient and thinking I must have hopelessly under exposed the plate, I thought, as an experiment, I would throw the plate into a developing dish which stood by, and contained hydroquinone, that I had just developed a number of lantern slides of the ordinary bromide kind. I was rather surprised to see the picture come up in less than ten seconds, the only fault that I could find was that it came up rather too quickly. The formula I was using was a slight modification of the one given by Messrs. Thomas & Co., and also Messrs. Fry & Co., both of which act well. The items I was using are as follows:—

Hydroquinone.....	165 grains.
Bromide of potassium	23 "
Citric acid	40 "
Sulphite of soda.....	1½ ounce.

ALKALINE SOLUTION.

Carbonate of soda.....	2 ounces.
Carbonate of potash	2 "

Make each of the foregoing up to twenty ounces of distilled water. Doubtless Messrs. Hough & Co. will issue a better developer than the above, as I have called their attention to the fact of this universal developer acting so well on their excellent Beechey plates. I forgot to mention that equal parts of each solution are to be used for a correct exposure.—I am, yours, &c.,

FRED. W. MUNCY.

"Oakleigh," 41, St. Julian's-road, Kilburn, December 31, 1888.

CAMERA CLUB EXHIBITIONS.

To the Editor.

SIR,—Will you allow us to draw attention to the second of the series of "one man" exhibitions of photographic pictures at the Camera Club? The exhibition now announced will be devoted to the work of Mr. Harry Tolley, of Nottingham. By the kind co-operation of Mr. Tolley we shall be able to present a fully representative show of his work, and believe that the exhibition will prove of great interest to photographers and artists.

The exhibition will commence on Monday, January 7, and will continue open for about six weeks. Visitors will be admitted on presentation of card.—We are, yours, &c.,

G. DAVISON, } Hon. Secs.
E. G. SPIER, }

Camera Club, 21, Bedford-street, December 31, 1888.

EARLY HISTORY OF THE LANTERN.

To the Editor.

SIR,—On receiving the JOURNAL this morning I read with great interest your extract from the *Manchester Guardian*, giving some early chapters in the history of the optical lantern. After describing fairly accurately the exhibitions which Messrs. Dancer, Manchester, Heywood, and Hutchings organised in the Manchester Mechanics' Institution, and the like of which had never previously been seen, the writer quotes at some length from an article published in *Chambers' Journal* (No. 284, July 9, 1859), entitled "Shadows in a New Light," which, he goes on to say, was "written by one of the brothers Chambers." This is an error which I desire to correct. The article in question was written by my uncle, Colonel Mellor, F.R.A.S., of Whitefield, near Manchester. I have a copy of the article by me as I write, and the contribution was suitably acknowledged by the Messrs. Chambers. I did not see the article in the *Manchester Guardian*, or I would have corrected the mistake.

Colonel Mellor was working in lantern matters with Mr. Dancer thirty years ago, when, I believe, about 5s. 6d. each was the price then paid to Negretti & Zambra for the splendid series of Frith's Egyptian slides, which he describes in the article in *Chambers*, and to which description the writer you quote alludes.

I very well remember being at my uncle's house one evening, some twenty years ago, when Mr. Dancer brought a novelty in the form of his (then) new diagonal lantern. After dinner we adjourned to a neighbouring school to try the new innovation, which, in this form of lantern, will be ever associated with Mr. Dancer's name.

Twenty years ago my uncle constructed a pair of metal cylinders, and fitted up a pump for compressed gasses, he also devised a regulator, which worked by the rise and fall of a column of water; his ideas have to-day been popularised in the modern bottles and patent regulators. I think therefore that Colonel Mellor's name might justly have been included among those of the early lantern pioneers.—I am, yours, &c.,

Lytham, December 29, 1888.

EDWARD W. MELLOR.

COPYING PAINTINGS.

To the Editor.

SIR,—Mr. Dunmore preaches up the value of common sense. On that point all sensible people will agree with him; it is an essential auxiliary, but it is not a substitute for technical knowledge; it will not enable a man to paint a picture or produce a photograph. He writes, "We are all aware that *damp long continued* is a very destructive agency, and will actually decay canvas itself," yet he still adheres to, "as a preliminary to photographing, the plan of sponging over the surface of the picture with glycerine and water or beer, leaving it moist while copying, either plan tends to equalise the surface."

The difficulty of copying old oil paintings is very great, and many negatives might have to be taken in the attempt to get a good copy; wet collodion is often used for copying, which would prolong the time; orthochromatic plates are still in the experimental stage, which would also involve a long time; the picture—if cracked—would be ruined. If glycerine were applied, I believe it never dries, and it would certainly ensure "that damp, long continued . . . will actually decay canvas itself." I still fail to see how these instructions can be consistent with common sense.

"Free Lance," in his letter on this subject, says of me. "He states that stout would be much safer than water, and that his modified egg-nog would not be injurious, which water might be; he is self-convicted of incompetence or want of veracity." The words in my article were in regard to stout, "I certainly would not recommend it, but it would be much safer on a cracked picture than his distilled water, and much less fluid and searching." Then, as to "his modified egg-nog." Now, although stout and egg-nog in moderation may be very good things by themselves, when mixed together as "Free Lance" mixes them up the mixer's notions on art are apt to become mixed also. Still, with all his egg-nog, he is not happy. He continues, "I never recommended, as he again suggests, after my disclaimer, that water should be used as a temporary glaze to facilitate copying." As he next suggests that I did not quote sufficient from Mogford, I shall now quote the entire paragraph from "Free Lance" which I quoted in my first article, omitting the first and last sentences, because I did not think them necessary at the time. I italicise some words to make the matter more clear.

"In the same number of the JOURNAL wherein this article is printed I notice a reference to pictures of another class that often seem to give trouble to the inexperienced—oil paintings brought to be copied, I mean. Now it is all very well for the expert to paint the surface with beer, or stout, or glycerine, or linseed oil, or poppy oil, or anything that suits his purpose; but I have to say that if a picture of mine were so treated without permission by one who was not to my knowledge thoroughly conversant with, and with the handling of, paintings, and I happened to be allowed into the studio while it was being done, there would be an instant opportunity for studying early English, and a great chance of a policeman being needed to prevent bodily injury to that photographer."

He talks of literary propriety and self-respect; where were they when he suggested that his style of language and conduct would be such that it might be necessary to send for the police? He concluded the next paragraph with, "No; let the inexperienced beware of anything but a clean sponge and distilled water upon the face of an oil painting." Now this discussion was solely founded on that portion of Mr. Dunmore's article on copying oil paintings. "Free Lance" says, "Oil paintings brought to be copied, I mean," and to these he mentioned the application of a sponge and water to facilitate copying. That in many cases would lead to saturation; he gave no caution or limit as to its use, and it was not till after I pointed out the danger, that in his next article he said he only meant a damp sponge for removing surface dirt.

My quotation from Mogford was too long, and I left out a distinct previous sentence, because, although it added strength to my case, it was not necessary, as it touched on "lining"—a distinct branch.

My reference to stout was, of course, confined to what had been written during the present controversy. I was not aware that any photographer, prior to "Free Lance," had suggested the application of such a dark, non-actinic liquor to a painting for the purpose of copying it.

In regard to "advice" to artists, I merely expressed my own individual

opinion when I said "I think" so-and-so, taken in connexion with my previous sentence (which "Free Lance" again ignores). "Of course, he will use his own discretion." It could not fairly be considered as giving "advice." I am, yours, &c.,
PICTOR.

Exchange Column.

* No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

I will exchange 15 x 12 mahogany-backed folding camera and two slides; want posing chair, two or more backs, and good interior background.—Address, GEO. SHERMAN, Photographer, Great Yarmouth.

Wanted, rustic arm chair in exchange for *Fragments of Science* and *Faraday as a Discoverer*, by Tyndall, and *Faraday's Lectures on the Chemistry of a Candle*.—Address, NESTLE, 4, Carlton-terrace, Harrow-road, W.

A number of baths and dishes, a pine studio stand, C.D.V. rolling press, and rustic stile; want background or accessories. Also retouching desks and printing frames up to 15 x 12, want wide-angle lens or camera.—Address, W. C. CHIFFER, 39, Highgate hill, London, N.

Will exchange a Ross' plano-convex lens, seventeen inches focus, for a pair of portrait lenses, about four and a half inches focus, for use with lanterns; also a large die press by Marion for a clockwork magnesium ribbon lamp.—Address, ALEX. AVERHOES, Photographer, Elgin.

Answers to Correspondents

* Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

M. R. C.—Try either hydrochloric acid (diluted) or a solution of oxalic acid.

F. R. (Boslington Quay).—There is a recently issued work by J. Hubert, price 6d.

POTASSIUM.—The potassium meant is what is popularly termed caustic potash. The other solution will keep and can be used several times.

THOS. J. O'CONNOR.—The toning and fixing proceed concomitantly. Follow the directions given and if anything is found to be wrong let us know.

A. J. GRIVITT.—The process is now open to the world, the patent having long since expired. A full account of it is given in the last edition of *Hartwich's Manual of Photography*.

A. R.—Add a little nitrate of silver to the distilled water, and if it does not show turbidity or does not become discoloured when exposed to light it is pure enough for ordinary photographic purposes.

GEO. A. JACKSON.—When the "steeling" of engraved copper plates is spoken of it is not implied that it is a real steel deposit, but only that it is coated with iron under such electrical conditions as to render it as hard as steel.

T. J. R. says: "There is a church in my neighbourhood that has been altered considerably lately, and as a large sale of views of it is anticipated I have been asked by the rector a certain sum for the sole right of photographing the exterior. In case I agree could he legally restrain other photographers being taken or sold, supposing mine to be registered?"—Registration will not prevent any other photographer from taking views of the church and selling them. It will only operate in preventing your own prints being copied.

LESTER COE, R. writes: "I have a lantern containing condensers of much larger diameter than the photographic transparencies I intend showing. A friend informs me that there will be a serious loss of light, and that I ought to obtain smaller condensers. Is he right?"—In reply: If the small transparency is placed near to the condenser, then will there be a loss of light equal to the area of unused condenser; but if the transparency be removed from that position and brought into a narrower portion of the cone, then will the illumination be all that can be desired.

J. R. asks the following questions: "1. Is it practicable, commercially speaking, to use the electric arc light instead of daylight for copying, enlarging, or reducing, by the wet collodion process?—2. Are the negatives as good as can be got by daylight?—3. What candle power is required to give good results?—4. What type of dynamo and lamp is best suited to the purpose?"—1. Yes; a very large proportion of the commercial work in copying and enlarging is done by the arc light.—2. Yes, if the light be evenly diffused over the picture to be copied.—3. This will much depend upon the size of the work to be copied. From 3000 to 6000 c.p. will suffice for almost every purpose.—4. A continuous-current dynamo. Messrs. Siemens Brothers will supply a suitable machine for the purpose.

LIVERPOOL inquires: "Can you oblige us with the address of a firm who can make for us micro-photographs mounted in miniature ivory mounts?"—We are uncertain. Some one possessing the information will perhaps reply.

M. writes: "1. In Piquet's book on enamelling, page 15, it says, 'Preparation of the collodion:—Alcohol, 400 parts; sulphuric ether, 600 parts; gun cotton, 8 parts; castor oil, 8 or 10 drops.' Will you please say if methylated alcohol and methylated ether will do for it, and if anything more is necessary than just putting the gun cotton in and allowing it to dissolve?—2. Also on page 575 of new ALMANAC, at the bottom of the page on intensifying, it says, 'Add 240 grains of sulphocyanide of ammonium: a precipitate is formed which is again redissolved.' Will it redissolve itself on shaking, or what do I add to redissolve it?"—In answer: 1. The methylated liquids will answer. In making the collodion, immerse the cotton in the alcohol, then add the ether and shake up well, when the cotton will dissolve; after adding the oil shake up again.—2. It redissolves upon agitating the solution.

ERRATUM.—In the first column of page 832 of our last issue, in the letter signed "John Hargreaves," the signature should be "John Hargreave."

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Ordinary meeting, Tuesday next, January 8, at eight p.m., at the Gallery, 5A, Pall Mall East.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of the Club, January 9, 1889, will be on *Hydroquinone as a Developer*.

We have received from the P. A. Co-operative Supply Association, Charterhouse-square, a sample of mounts made entirely in London, from the primary pasting to the last rolling, which serves to show that England can hold her own against Germany in this department of manufacture.

The premises of Mr. Holoway, Photographer, of Chester, were completely burnt out on New Year's Eve. Everything but one camera was destroyed, and as the studio, reception, and other rooms, were entirely of wood, and two stories high, it is a marvel that anything is left standing. We understood Mr. Holoway was fully insured.

MANCHESTER AMATEUR PHOTOGRAPHIC SOCIETY.—The Exhibition of this Society will be held in the Lecture Hall, Manchester Athenaeum. It is open on Tuesday, January 8, 1889, from six to ten p.m.; Wednesday, January 9, from ten a.m. to ten p.m.; and Thursday, January 10, from ten a.m. to ten p.m. There will be a lantern exhibition each evening.

SAMUEL FRY & Co. write: "Herewith we send you a sample of our compound sulphoquinone developer, and we send you at the same time a bromide print developed by its agency. This developer is universal in its application, and may be used for transparency and negative work with much success."—We have tried this "sulphoquinone" developer and have nothing but good to report as to its action. It brought out the prints very cleanly, the tone at first being a warm brown, which soon afterwards proceeded to a fine engraving-black. More than one print was developed by the same solutions, which we received in two bottles with instructions to mix them in equal proportions.

RICHMOND PHOTOGRAPHIC EXHIBITION.—We learn with pleasure that this is likely to be a very large Exhibition, and that exhibits have been sent from all parts of the country, including Scotland, Ireland, and elsewhere. We understand H.R.H. the Princess Mary, Duchess of Teck, is to open the Exhibition on Tuesday next, the 8th, at three p.m., and afterwards to attend the exhibition of lantern slides on the screen, when the "Optimus" prize, comprising a five-inch enlarging apparatus, offered by Messrs. Perken, Son, and Rayment, of Hatton-garden, for the best lantern transparency, will be awarded. A feature in the Exhibition will be the projection of lantern slides on the large screen, which visitors will have the opportunity of seeing, without extra charge, each day, at half-past four and half-past eight.

CAMERA CLUB FIXTURES FOR JANUARY 1889.—Monday, January 7, Opening of the Exhibition of Mr. Tolley's photographs (second of the series of One-man Exhibitions at the Club); press and private view, half-past seven to nine p.m.; nine p.m., Smoking concert. Thursday, January 10, eight p.m., Lantern evening; members are requested to bring new slides. Thursday, January 17, eight p.m., Mr. Andrew Pringle on *Photo-micrography*; apparatus and illustrations on show. Thursday, January 24, eight p.m., Mr. W. Marriott, of the Royal Meteorological Society, on *The Application of Photography to Meteorology*; illustrations on exhibition. Thursday, January 31, eight p.m., Mr. Graham Balfour: *Figure in Landscape and Genre*. Monday, February 4, eight p.m., Smoking concert. Thursday, February 7, eight p.m., Mr. J. E. Austin on *Enlarging*; illustrated by enlargements on Alpha paper.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1497. VOL. XXXVI.—JANUARY 11, 1889.

DEFECTS IN SENSITISED PAPER.

Our readers will understand by this title that we refer, not to "ready sensitised paper," the well-known form of expression for sensitised albumenised paper with keeping properties, but to the ordinary kind prepared the day it is wanted, or, at least, shortly before it is to be used. That there is an increasing demand for the former is beyond doubt, and also that pictures of the highest class may be obtained upon it the walls of the various exhibitions have shown; but when tones more approaching the "blue" stage are wished for, the preponderance of opinion is undoubtedly on the side of the ordinary paper. Lately there have been brought under our notice several examples of defects of a kind which had not before come within the range of our experience, and it may be useful, therefore, to call attention to them here. The presence of black spots has always been a source of trouble to the photographer, and of anxiety to the albumeniser, whose shoulders, like those of the dry plate maker, are too frequently made to bear the burden of want of skill in their customers and of the faults of the manufacturers through really the existing imperfections in the raw material, the paper itself. A little close and careful examination of a sheet of paper before placing it on the silver bath will in most instances, if they exist at all, reveal the presence of minute black specks either imprisoned within the texture of the paper itself or outside that surface and within the albumen. Some batches of paper seem to be more spotted than others, and at the same time some albumenisers are great sinners in this respect, the paper they send out being largely sprinkled with little dots of black, which, when the print is toned and fixed, cease to be little and spread into ugly marks.

Such spots as we describe, however, fall within the experience of most photographers at one time or another, and are traced without difficulty to their true cause. But when that happens to be external, and the markings resemble the familiar ones, there is room for conjecture, experiment, and often for dismay. The particular kind of defect which last came under our notice consisted of small, irregular black marks occurring only occasionally, and in a very erratic manner. An investigation brought to light the fact that, though in a week's work a decidedly large number of prints were spoiled, the damage of this particular kind was confined to two negatives, and a further examination revealed the fact that on each print from a particular negative the markings occurred in exactly the same place, showing almost conclusively that there was some abnormal action taking place through the negative itself. A close scrutiny showed that there was some—the very slightest

—irregularity of the surface, but nothing that would, under ordinary circumstances, have drawn attention to the spot. Revarnishing the negative proved a complete cure and covered the evil, whatever it was.

The next instance was a complete crop of these metallic marks, which make their appearance with such regularity and persistence as to become a most harassing trouble in the printing department of the photographer whose studio they invaded. Great difficulty was found in tracing them, although eventually the cause was discovered. A complete change in the pads brought temporary relief, but after a while the evil reappeared again, to be exercised by another change. It was found after a time that all the spots emanated from certain new frames recently taken into use; and ultimately the cause was proved to be the presence of minute, invisible, metallic particles, which found their way into the frame-back and the pads, or both, after the brass springs had been filed to shorten them, an operation rendered necessary through their being too long to fit in their places, except when the frame was empty of negative and packing.

The next instance we would record was, without exception, of any ever brought before us, the most mysterious, the most annoying, and productive of the greatest loss of material through so long a time elapsing before tracing the mischief to its source. The form of the spots was irregular, and the size most uneven, varying from markings no larger than a small pin's head to others from half to three-quarters of an inch long, and about an eighth wide; but all these proportions were irregular and uneven. Frames, pads, and negatives were subjected to the closest examination, till at last the conclusion was reluctantly come to that the paper must be in fault, and preparations were made for obtaining a fresh supply when our advice was asked. We knew the photographer in command to be an experienced hand, and one who was never tired of inculcating the necessity of cleanliness of manipulation in all matters connected with dark room or printing room; and we also know that he practised what he preached. It is needless to detail all that was done or left undone; suffice it to say that, after every possible source of evil was eliminated, the conclusion was arrived at that the mischief was introduced after drying and before printing, the irregularity and uncertainty of its appearance adding greatly to the perplexing nature of the problem. The cause of the spots was eventually made clear. After taking from the bath and drying, and before storing away, the paper was laid upon a table upon which clean paper was always placed; but at the time these markings arose the paper

employed for the purpose was old but apparently clean newspaper, and it was this paper that caused the marks. Apparently there was, either in the paper or the printing ink, some material which exercised a reducing action upon the free nitrate of silver. We could not discover what this was, but when the use of the printed sheets was discontinued the markings instantly disappeared and have not reappeared since, a space of time covering nearly six months. We find that we have not quite exhausted our subject, and leaving it for the present we therefore hope to take it up again shortly with a description of the cause of further abnormalities of marking.

CYCLING AND PHOTOGRAPHY.

Though the present is emphatically not the season to tempt the cycling photographer to venture forth with camera and steel—unless, indeed, it be a bright frosty day with the trees and hedges clothed in rime—it is decidedly the period when preparations may be made for another campaign, and we have, therefore, no hesitation in alluding to a subject which many totally shelve at this period. We have all the less compunction in the matter since the paper which forms our text is the comparatively recent one read by Mr. E. R. Shipton before the London and Provincial Photographic Association.

With regard to the purely cycling side of the question, we are scarcely so well qualified to speak as an old and practised cyclist like Mr. Shipton, who has also more than “served his time” in the photographic department. But as he has left two points in a somewhat unsatisfactory state, in connexion with which we can make one or two suggestions that we think will be found of value, we shall proceed to do so. The points referred to are the prevention of shaking and vibration, and of the access of dust to the films.

So far as the first is concerned, it would be, perhaps, as reasonable to expect to entirely annihilate the trouble as to carry an unlimited weight over any sort of road without any exertion. The very construction of the tricycle courts vibration, or perhaps we should say that the very features in its construction that commend it for ordinary travelling purposes favour that defect. In order to produce a machine that can be propelled with a moderate amount of exertion over ordinary roads it is obvious that the construction must be as light as is consistent with strength; if the framework be strengthened until vibration disappears, we should have a vehicle entirely unfit to be worked by a man, at least with ordinary comfort or any approach to it, so that what we can do is only in mitigation of the trouble at best. But if a good sound machine of the “roadster” build, and good type, be selected, much may be done in connexion with the “carrier” to make matters run with tolerable smoothness.

The method of carrying we adopted some years ago with an old form of rear-steering machine was to fix the photographic travelling case by means of stout straps to the framework of the machine, not binding it to the machine itself, but suspending it from different points and tightening the straps as much as possible, until it occupied much the same position with regard to the framework that the hub of one of the wheels does to the rim. In this manner, while the rudest of the jolting caused by uneven roads, and much, if not all, of the vibration were expended upon the framework of the machine and the connecting straps, the camera was not subjected to any undue amount of swing, as would be the case with too light

springs, and which would be as bad as the original disease. It is not every form of machine that will permit of this arrangement we are aware, though some which *per se* are not so utilisable may be easily made so. Thus, with another machine of the “Premier” type which we rode for some time, though we were unable to strap the apparatus to the cycle itself in the manner described, we managed with the assistance of a single luggage carrier of the L form to establish fresh points of suspension from which to hang the straps, and thus, between machine and luggage attachment, we were enabled to attain the desired end. Similar expedients will, no doubt, prove equally effective with other types, and a good opportunity will be afforded at the end of the present month in the Stanley Show at the Crystal Palace to examine some thousands of cycles of the most modern forms, and to make a selection of those which appear most convenient in themselves, or offer any suggestions which may be applied to others.

It is alleged that the constant jarring and vibration of cycling will in a comparatively short time so loosen the lens in its cell as to necessitate its being remounted. This is a somewhat serious matter if it be true under circumstances where proper precautions are taken; but we have never experienced any symptom of such a result, nor have we heard of an actual case—possibly because our own cycling practice with the camera and that of our friends has not been of a sufficiently constant character. But where such a trouble should make its appearance we would suggest that the lenses be carried separately in a bag or satchel fastened securely to the body of the rider, not merely slung to a strap—in which case a good deal of shaking from swinging would ensue—but attached firmly by means of a belt. If, under such conditions, sufficient jar or vibration were transmitted to the lens to loosen it in its cell in any reasonable time, we imagine that it would require a miraculous constitution to enable the rider to survive the destruction of his lens. We have carried a “sitting” of eggs for hatching a distance of over five miles in that manner over indifferent roads, and nine out of the dozen subsequently hatched all right, which, from a poultry-breeder’s point of view, may be taken as a tolerably severe test.

For the rest, if the things be slung in the manner described—and, in addition, the precaution mentioned by Mr. Shipton be adopted of securely and firmly wedging each article into position in the case, so as to prevent its jumping about—we do not think much trouble on the score of shaking will be experienced by even those who do much more cycling than the majority of photo-riders. The great danger arises from careless packing and unsuitable means of attaching the apparatus to the machine, and under similar conditions equal injury would accrue in almost any vehicle travelling over rough roads.

The second point, the avoidance of dust, is one which, though it may cause a great deal of annoyance in a general way, is not so difficult to battle with if attacked in a methodical manner. Dust, we are all aware, is a great bugbear in photography, but in connexion with cycling the conditions are in every way more favourable to the development of the trouble than in almost any other department. Given fine weather and more or less dusty roads—conditions almost sure to prevail on the best “photographic” days—and add to these that the apparatus is trailed along at little more than a foot or so from the ground upon a lightly built fabric which, by its vibration and jolting, adds to the penetrating power of the dust particles, what wonder is there that every nook and crevice, and every fold of raiment, becomes thoroughly imbued with the objection-

able matter! The finest workmanship of the camera maker, the closest-fitting slides and shutters, are alike powerless to keep out the enemy by themselves, and it becomes absolutely necessary to adopt some special means to combat the ever-present foe. Still, we repeat, this difficulty is not so formidable as one to meet as that already dealt with; and we can say, with Mr. Wollaston, that though we have developed many negatives taken on cycling trips, we have never experienced any serious trouble from dust.

Such remedies as that tried and rejected by Mr. Shipton—smearing the rabbit of the dark slide with glycerine—are likely not only to fail in the object aimed at, but actually to increase the difficulty, whilst the beneficial (!) action upon the dark slide alone forms a powerful item in the calculation of the advisability of adopting such means. We venture to think that no wooden slide so treated, with sufficient hygroscopic matter to be of any use as a "dust trap," would, after an hour or two of a hot July day, permit its shutters to be withdrawn; and even if they were so loosely fitting when dry that they could be forced when swollen, the constant change in the condition of the woodwork from repeated applications of the glycerine would speedily ruin the best apparatus.

It was perhaps more the result of a happy accident than through any previous calculation that we secured a comparative immunity from dust in our cycling experience. Our first excursion with the camera, a day trip of only some twenty or thirty miles, was made on a particularly hot and dusty day in the middle of summer. Having had some experience of the effects of dust upon external appearance when cycling, before starting we slipped into the camera case a small hat brush with which to remove the thick of the dust from our clothes previous to passing through any civilised or populous regions. That formed part of the accident, while, to complete it, it happened that we carried each of our double slides in a closely fitting bag or envelope formed of two thicknesses of black twilled calico, made nearly twice the length of the slides, so as to fold over and thoroughly exclude all light until inserted in the camera underneath the focussing cloth. The camera case being unfitted with partitions, the camera was, as a rule, wrapped in the focussing cloth to protect it from rubbing against the other contents, as well as to fix it firmly in position, so that as far as possible every obstacle existed to the ready penetration of dust into either camera or slides.

Upon first opening the case after a run of eight or ten miles we found the contents "white" with dust, and naturally, having the means at hand, removed it by means of the hat brush already mentioned before removing each wrap, and this formality was gone through at each stoppage. Without attaching any particular importance to the matter, we subsequently continued the practice, carrying the brush for the special purpose on all our photo-cycling excursions, and to this we attribute the fact that dust has never been any more of a trouble to us on such occasions than when travelling on foot. In fact, if the plates and apparatus are properly dusted before starting, these simple precautions will remove all further need for anxiety.

Another plan which we adopted on one occasion many years ago, before the cycling era, may prove even more effective. The time was July, the weather hot and dry, and the *locale* the English Lake District. We had had a whole day's work, the result of a tramp of some twenty miles, entirely and hopelessly spoilt by dust, so we resolved to stop the evil if possible. Procuring some sheets of stout brown paper and some paste, we

made half a dozen "envelopes" to fit the slides, and also one for the camera, pasting over the joints with the exception of one side, which was closed with a broad flap. This flap and the adjacent portion of the envelope against which it would lie when closed were smeared with—nothing better being obtainable on the spot—common treacle, which caused the flap to adhere tenaciously to the body of the envelope when closed, and yet to be easily opened and reclosed when necessary for exposure. After very carefully dusting and ventilating the camera and slides, these roughly formed "protectors" stood the test of a walk from Ambleside to Keswick and Borrowdale and back again on two of the hottest days we ever remember, and dusty in proportion, and we had not the slightest cause to complain of dust spots.

For regular use, while adhering to this principle, we intend to modify the details of construction, making the envelopes of stout Willesden paper, preferably covered with twilled calico for the sake of durability. Instead of treacle, which is inexpressibly "messy" in use, we propose to apply to the flaps a mixture of gelatine and glycerine similar to that used for the different "graph" copying processes; this, while very adhesive, may be so nearly dry as to cause no trouble or mess, and if it get too dry only needs moistening with a sponge or rag and a little water or glycerine and water. The camera as well as the slides should be so "cased," for it is little use keeping the plates themselves free from dust before exposure if during that operation the interior of the camera is full of floating particles. It is, of course, impossible to entirely exclude dust from the camera when inserting the slide, but at least there is less chance of the film being contaminated if we start with the internal atmosphere comparatively free than if it be already overloaded with dust.

Dust is omnipresent and omnipotent for evil, but with envelopes so constructed, and the joints, both fixed and temporary, made thoroughly sound, we scarcely think the most "rickety" of tricycles would produce any very serious effect if the surfaces of the plates, as well as interior of camera and slides, are free to start with. Now is the time to construct the protectors, and put them to any tests that may suggest themselves, in order to ensure efficiency when the time comes for their use.

ALREADY has the Council of the Photographic Convention of the United Kingdom taken steps to ensure the most ample accommodation for the various meetings and exhibitions which will be held on the occasion of the next gathering. Having been *en rapport* with all the large halls in London, they considered that the balance of advantages lay in St. James's Hall, Regent-street, and the Great Hall of that edifice has accordingly been secured. The position is central and of easy access from all parts, while the accommodation is most ample. The time for the meeting has been fixed for the week commencing August 19. Further details will be duly announced.

THE year just ended was a remarkable one in a meteorological sense, as every photographer is fully aware. Last week we alluded to a paper read before the Meteorological Society by the Rev. T. A. Preston, M.A., showing the abnormally low temperature which had prevailed up to the latter part of October. However, after the short spell of severe weather at the commencement of that month, a much milder and almost spring-like temperature set in and continued till the end of the year. The Annual Report just issued from the Meteorological Office will no doubt take many photographers by surprise, inasmuch as it shows that the mean temperature for the entire year was but one degree below the average. This may be accounted for by the fact that, although the summer was much colder than

usual, the temperature at the latter portion of October and during the months of November and December was far above the average.

ON the commercial aspects of photography during the past year we find, on inquiry, that opinions somewhat differ, but, on the whole, it is said to have been satisfactory. Many portraitists say that the last was the best year they have had for several past. The high-priced and the very low-priced professionals appear to be the best satisfied with the year's results. It is the medium-class houses which complain the most of depressed business. It would almost appear, from observations during the past few years, that commercially successful photography, as regards portraiture, is becoming divided into two distinct classes, namely, the very high class and the mediocre. It is the intermediate grade that, in a business point of view, seems to be in the least satisfactory condition. It is those who follow the latter class of business that complain the loudest of the influence of amateur photography on their trade, and many are not slow in attributing their diminished returns to that source.

TELEGRAMS received since the different eclipse expeditions in America have had time to more closely examine, and, to some extent, compare results, fully confirm those sent earlier, that the observations made were eminently successful; also that the majority of the large number of negatives secured have turned out satisfactorily. There is no question that the results obtained on this occasion ought to prove of immense value to astronomers.

ALTHOUGH, up to the time of writing, photographers have had no opportunity of obtaining pictures of snow-clad landscapes, the recent fogs have been productive of some exceedingly heavy hoar frosts which have given the country a very picturesque appearance. Frost-covered trees and shrubs make glorious pictures. Unfortunately, however, hoar frosts are usually accompanied by such foggy weather as to make the photographing of them somewhat difficult at times. With near objects, however, little difficulty will ever be experienced. If orthochromatised plates be employed the intervening fog will, to a modified extent, be ignored.

IN pictures of frost or snow-clad landscapes it is quite a mistake to imagine that a certain amount of fog in the distance is a disadvantage, as, on the contrary, it greatly enhances the wintry effect, while, at the same time, by contrast, it gives greater brilliancy to the nearer objects. Hoar-frost effects make charming lantern slides; so they do stereoscopic pictures. A group of ferns, or similar objects, covered with the sparkling crystals, form excellent subjects for stereoscopic photography. There is scarcely a suburban garden that just now would not yield some excellent frost pictures. Photographs of hoar frost are always more effective when printed as transparencies than when they are on paper. By backing the transparencies with different tinted glasses a great variety of effects, such as moonlight, glowing sunlight, &c., can be obtained, particularly in the lantern.

RECENTLY a considerable number of letters have appeared in some of the daily papers commenting on the large proportion of the Christmas and New Year's cards sold this season, which bear the imprint, "Designed in England, printed in Germany." This intimation is, of course, necessitated by the exigencies of the Merchandise Marks Act, which, as regards this class of goods, appears to be rigidly enforced. Why should it not be so in the case of photographs? There are numbers of collotype prints, from negatives taken here, being supplied which are really printed abroad, although they bear no intimation of the fact; consequently they are passed upon the uninitiated as being of home production. If the Act were enforced with regard to these pictures they would bear the words, "Photographed in England, and printed in Germany." In future we anticipate this will be the case, as we learn that some short time back a large consignment of foreign collotypes were arrested by the Customs authorities because they did not bear an imprint indicating the place of origin.

ON THINGS IN GENERAL.

WHEN the value of the work done in 1888 comes to be reckoned up in the future, the mode of printing in platinum by the so-called "cold process," and the great attention given to hydroquinone and its properties, will occupy a foremost position. There cannot be a doubt that platinum printing has received a distinct impetus, and been brought to a degree of excellence beyond all its previous achievements. It has so many points of sterling value, that all lovers of the beautiful must welcome every variation, however small, tending to increase the excellence of its results. To my mind its greatest claim to attention is the fact that for negatives of inferior quality it is not suitable. When results of the highest class are aimed at, none but negatives capable of producing good prints should be kept; then platinum will make "a thing of beauty" and "a joy for ever" of them.

Hydroquinone also will have a place in the future of photography. Whatever opinions may be held as to its quickness or slowness, there can be no doubt as to the pleasing colour that can be obtained from its use, provided only that it be combined with plenty of sulphite. For lantern slides there is a strong probability that it will become very popular.

Apropos of lanterns, it is amusing to note the latest thing in penny help-yourself-stands. We have had proposed a machine to photograph the penny-dropper "while you wait;" but so far it exists on paper only, and is likely to. In Paris, however, they have produced an electric magic lantern. The coin, dropped through the slit in the usual manner, immediately actuates an electric battery for a few seconds, and at one time produces the necessary illumination and sets a series of views revolving. The eye is placed at the peephole, and the show is for a brief period visible, when the light extinguishes itself till another coin once more sets it going.

I should like to draw the attention of those of my readers who have not seen it to a letter from the veteran, Mr. Alexander Forrest, in the correspondence columns of the last number of this JOURNAL, for the year just ended. It recommends, and describes how, for one extended locality, there has been carried out a photographing of the whole of a "hundred" county, or other division, by dividing it into sections, the photographing of each section being undertaken by one or more members of the Society. A survey of a complete district is thus obtained, and for future reference, and present amusement and instruction, will be invaluable. The photographing of a section is, of course, a very wide term, and may be taken in a different sense, according to the views of the photographer undertaking it. An improvement in the plan would be the separation of the undertaking into subdivisions: one to embrace objects of archaeological and antiquarian interest, another to include geological features, a third natural history, a fourth purely pictorial, and so on. The results would be more systematic, and likely to prove of greater value.

The discussion on artificial modes of illumination for enlarging purposes at the North London Society, as reported on page 830, was both interesting and instructive, the President's method of producing an even sheet of lighting surface by placing before the negative a sheet of obscured glass, illuminated by three gas jets, being both simple and efficient. It might be improved by an opal reflector, curved, if possible, to render the illumination more even. Most people have seen a clock in some public place or other illuminated by the same means. When unaided by a reflector it is a very miserable affair, especially after the "ground glass" has been in use a little time; the illumination is not even, and the outline of every individual light is seen through the semi-transparent screen of glass. But when the lights are backed by a reflector that may be likened to a white bowl, the inside turned to the flames, the contrast is very great, from grossly uneven to wholly even. Of course, in the lighting of the photographic arrangement alluded to this great disparity would not exist, as the flame areas would be quite out of focus, and so dispersed and amalgamated with one another.

It is somewhat singular that so little has been heard of the deterioration of lenses by the continued action of air and moisture, and photographers would do well to note the remarks by "L. P." as seen on page 821 in the number of the JOURNAL already quoted. That glass is acted on by moisture is well known, although in many cases it is so slow as to be a negligible factor; but, especially in the early days of the symmetrical and rectilinear type of lens, glass was used

whose qualities were not fully known, and which was given to "sweating": it is obvious the surface would rapidly be injured when this occurred. But all lenses should, indeed, be well protected from the atmosphere if their pristine qualities are expected to be retained, whatever the kind of glass used—crown or flint, sweating or permanent.

Those who are in the habit of using magic lanterns with paraffin oil as the illuminant, especially when their use is only occasional, will do well to follow Mr. Haddon's advice as given at a recent meeting of the London and Provincial Photographic Association. He says: "One way of avoiding smell in subsequent operations is to carefully empty all paraffin from the lamp at the close of each exhibition, or otherwise, by capillary attraction, it would continue to rise in the wick, and afterwards run down the side of the lamp." This is quite true, and not only does it so run, but by some special action it appears to travel over the whole surface of the lamp; and if the latter be put away for a time and then used, the evaporation from the surface of the heated metal of the lamp becomes terribly offensive. A lamp so tainted should be lighted in an outhouse, and allowed to burn for some time before being brought into an inhabited room. This smell is sometimes put down to faulty construction of the lamp, when, indeed, it is nothing but the burning and the volatilisation of the film of oil.

I have been interested in reading Mr. T. N. Armstrong's articles upon instantaneous work, but I can scarcely coincide with his views as to the quality of quick plates now in the market. I have tried nearly all the best brands in a thoroughly systematic way, and I may say that I believe I am now using the quickest plate sold yet; but so far from their giving thin negatives, I have had to reduce the strength of my pyro (as used with some other makes) to bring them under sufficient control when I develop about half a score at a time. The finished negatives, too, are all I desire, as regards gradation and density combined.

I suppose the correspondence with "Pictor" may now be considered at an end, as in his last letter he makes no attempt to disprove the charge of want of veracity or of competence, and does not explain away the ignorance he displays on the subject of drying oils.

FREE LANCE.

ECHOES.

I WROTE, last week, of copyright and the ownership of the negative, and I find in the same number a couple of letters on those subjects. In the first, J. Hubert, taking the "Pollard Case" as his text, pleads in favour of the proposed co-operation of professional photographers in the formation of a Trade Protection Society, against which I, personally, have nothing to say, but his suggestion of the starting an "appeal fund" in this particular case will scarcely commend itself so strongly. As a friend or acquaintance of the defendant, Mr. Hubert actually takes a strong view of his side of the case, and the version of the facts as given by him may be perfectly accurate; but even so, it is not very clear to me that an appeal is by any means certain to bring about a reversal of the decision, for, leaving the question of copyright altogether on one side, I venture to think that no judge would rule that a photographer has the right to publish any lady's portrait without her permission. The application was, it must be borne in mind, for an injunction to restrain further sale; if the defendant chooses to plead copyright, or, in other words, that he has a perfect right to do what he likes with any portrait he is paid for taking, without the sitter's permission, I think he will find very few even, amongst respectable photographers, to side with him.

But the point in Mr. Hubert's letter to which I would especially call attention is where he says, "It has always been understood by photographers that the copyright is vested in the operator and not in the sitter." Is this so? I think not. So far as the very ambiguous law on the subject can be interpreted in any definite manner, I was under the impression that it says pretty distinctly that where a photograph is taken "for a consideration" the copyright belongs to the party paying; in other words, that the copyright in a portrait taken in the ordinary way of business belongs to the sitter. So much is this the case, that I know at least one photographer of eminence who takes many portraits of celebrities purely for publication and without the usual "consideration" who never proceeds to registration

and publication until he has a written assignment of the copyright in the portrait. This of course is in addition to the permission to publish, which, however, might be assumed if the sitter consents to be photographed; but the assignment renders matters sure and prevents the subsequent withdrawal of the right of publication—a right which never exists under the circumstances of "consideration."

As for the imaginary difficulties which might arise on the suppositions cases mentioned by Mr. Hubert, they could only be possible where a malicious intention of annoying or imposing upon the photographer existed, and even then would be easily disposed of. For instance, in the hypothetical case of a group of twenty, some one individual must almost of necessity have ordered and paid for it, and consequently be the owner of the copyright as having parted with the "consideration." Or if each member of the group paid for his own copy or copies, he has an equal right with every other member of the group to order fresh copies without harrowing the soul of the nervous photographer.

In the letter signed "F. J. Q.," which is, I suppose, intended to be facetious, the writer overlooks the absence of "consideration," consequently the idea that an *unconscious* sitter has any claim either to the copyright or to the negative itself (which "F. J. Q." mixes up) falls to the ground. If the picture so "poached" be in any way objectionable, the "sitter" would have the legal means, I presume, of preventing its publication, but under no stretch of ingenuity could he claim more. It would perhaps be better if he could, as the indiscriminate users of secret cameras might then perhaps have an inducement to be careful as to the manner in which they apply them.

I am not sufficiently versed in the mysteries of psychic photography or spirit science generally to feel myself qualified to criticise Miss Power's letter on the subject, nor justified in making any suggestions regarding the negatives forwarded to the editor, especially as I have not seen them. I am, in fact, a sceptic in such matters, though I am far from being an unbeliever in "spirit photographs" provided they are of the kind referred to and described by Mr. W. K. Burton. I have, in fact, such faith in "psychic" photographs of that class, having met with more than one such mysterious visitation in my own experience, that I scarcely care to search deeper for the influence that produces them than dirty plates and similar dodges; and while I do not wish to impute dishonest motives in all cases of spirit photographs, I am bound to say I think imagination has much to do with their genuineness in most cases.

But Mr. Burton's story is one of the best I have heard, and it is fortunate in the interests of truth that so great an authority was able to trace such a mystery to its source, otherwise we might have had Burton at some future date ranked among the firm believers in the capabilities of the "spirits," not only in portraiture, but in landscape and interior. Spiritualism has ranked amongst its believers more than one high scientific authority, who having witnessed manifestations that were unexplainable, elected to set them down to spirit force rather than doubt the *bona fides* of the manipulator or medium. Had our friend Burton's mysterious photographs been obtained on the plates prepared in this country, it is to be feared they would have gone to swell the evidence in favour of the spirits, but as it was the local circumstances were such that the truth prevailed.

One thing, however, strikes me as curious in Mr. Burton's letter, namely, that he appears never previously to have met with a duplicate image so produced upon a dry plate—that is, upon a gelatine plate. He speaks at least of its being the first *recorded* instance, and I judge the phenomenon therefore to be new to him, which surprises me the more since I know him to be one who has certainly not made all his pictures upon commercial plates, and who has presumably sometimes recoated glass that has been used before. The reason why such occurrences are so rare nowadays is no doubt due to the fact that it is cheaper for the plate maker to use new glass than to clean off old, and consequently there are very few old images to reappear as ghosts or spirits. But that they will do so I had reason to discover some few years ago when I invariably made my own plates, experimental and otherwise, and of course used my glass over and over again. I then found it a great trouble to prevent the recurrence of previous images on some plates, though not by any means on all, and this partiality in the matter I attributed to the

kind of glass; that is to say, its character as regards porosity or otherwise of surface.

I can quite conceive even the reappearance of an image after all the lapses of time and all the cleaning process mentioned in Mr. Barton's letter, without going to phosphorescence as an explanation, for I recollect one particular plate that was constantly turning up at awkward times with one particular old image and not intermediate ones. It resisted all my ordinary methods of cleaning, until I made a special bath of bichromate of potash and sulphuric acid chiefly for its benefit, and thought I had at last "laid" the ghost. Not so, however, for it turned up once more in combination with one of three pictures I had travelled many miles into the country to secure; so to save further trouble that plate was destroyed.

It may seem curious that one image should so impress itself and other subsequent ones not so, but in reality I do not consider it so, especially in this instance. At that period I was deeply engaged in investigating different methods of intensification with silver, mercury, copper, platinum, and what not, and though I had no record by which I could tell the history of my phantom image, it is almost certain that its persistence arose from its having been treated—perhaps forced—with some more than ordinarily strong metallic solution, and had so obtained a correspondingly firm hold of the glass. The frequent, I may say regular, recurrence of such images at that time may also no doubt be ascribed to the same general cause—the systematic use of metallic intensifying solutions—because though even at the present day I still make a practice of preparing some of the plates I use, it is a very long time since I remember a case of redevelopment of a previous image, and nowadays I very rarely resort to intensification of any kind, finding the alkaline developer performs all I require.

A very interesting communication by Mr. J. W. Osborne to the Society of Amateur Photographers of New York, on the subject of *Surfaces Freely Sensitive to Light*, contains a reference to "a few salts of iron and platinum" as being amongst the sensitive materials ordinarily used in practical photography. Now I have racked my brain, and though I can call to mind innumerable processes old and new, practical and obsolete, in which ferric salts figure as the sensitive agent, I cannot think of any application in a similar manner of a platinum salt. I may, of course, be wrong, I may have overlooked some familiar process, or, what is very possible, some such process or application may exist of which I am altogether ignorant, but at present it seems to me that in including platinum salts Mr. Osborne is erroneously referring to the platinotype process. In the original or hot bath process it is true that the platinum salt formed a part of the sensitising solution, but it in no sense takes any part in the formation of the image until the developer is applied. In other words, it is not sensitive to light, while at the same time it is not a developer, but merely suffers reduction by the developer formed by the action of light upon the sensitive ferric salt with which it is combined, which action is not set free until the insoluble ferrous salt so formed, and which constitutes the real developing agent, is rendered active by the hot solution of potassium oxalate which is ordinarily called "developer." In the "cold bath" process the platinum salt is not present at all in the sensitive paper, but forms part of the developing solution.

Mr. Osborne's remarks on the darkening of white papers under the action of light are interesting, and the results not so generally known as the bleaching of aniline coloured papers. With regard to the length of time required for the bleaching or the sensitiveness of the dye, the author's experience differs considerably from my own, at least so far as regards eosine, for I have met with a sample of that dye a solution of which, of the strength of one per cent., when washed over ordinary writing paper, had its colour completely discharged in little over an hour's exposure to sunshine, and showed an appreciable change in three or four minutes. The sample I refer to was one possessing special "orthochromatic" powers, more so in fact than any similar dye I have since been able to secure. Erythrosine I have not found so sensitive to the bleaching influence, nor does it exhibit so great efficiency for orthochromatic purposes.

Mr. Osborne also alludes to the darkening of wood by light, and states that the effect is often attributed to exposure to the atmosphere. All photographers are familiar with the darkening action

that occurs in cameras, the rich light yellow of the new instrument changing in time to red of greater or less depth. I formerly attributed the change, and no doubt many others do, to atmospheric influence upon either the wood or the polish, or both, but that it is a photochemical change is, I think, proved by a careful examination of a camera that has been exposed for any length of time in a show-case, especially if in a strong light. While the general colour will be comparatively dark, underneath the sliding plates and other movable brasswork the original light tint will prevail, and it can scarcely be supposed that these offer any or much protection from the atmosphere, though they do undoubtedly from light. Again, a mahogany studio camera which is constantly exposed on its stand in the glass room will be found generally darker and to darken more rapidly than a landscape instrument which spends most of its time shut up in its leather case. JUNIUS.

VIGNETTING.

THERE is, perhaps, no more delicate or artistic manner of printing a photograph than vignetting it, if it is properly done. A badly vignettied picture is an abortion, and of all eye-sores one of the most irritating. The comparative ease with which a good vignette can be made ought to prevent any but good work being sent out. That it is not so we are most of us painfully conscious. The difficulties to be encountered are few, and to be overcome more by careful working than manipulative legerdemain, providing the negative itself is suitable. One of the chief causes of bad vignettes may, I think, be attributed to the use of negatives utterly unsuitable for the purpose. Unfortunately, the exigencies of portraiture necessitates the occasional use of negatives that were taken without any reference to being vignettied for this mode of finishing, and much of this unsatisfactory work may fairly be attributed to this cause. Given a suitable *cliché*, vignetting is tolerably plain sailing. A screen, with a suitably shaped opening, with serrated edges laid outside the printing frame, will generally answer every purpose, the graduation of the vignette and its size being dependent on the distance of the screen from the negative, and the fineness and length of serration. For the best results the printing should be through ground glass or tracing paper, and the operation conducted in a good strong diffused light; under certain conditions sunshine may be used, but of course the sharp shadow of the screen must be diffused by extra thicknesses of tracing paper; but, take it altogether, nothing is so good as strong diffused light, as in direct sunshine the additional tracing paper used counteracts the extra strength of the light. Perhaps the very softest gradations are obtained by the use of two serrated masks, each covered with tracing paper and adjusted with a space of about half an inch between them, but for ordinary practice one screen is sufficient.

We will suppose a suitable negative is to be treated. The first thing to be done is to decide on the *shape* of the vignette—whether it shall be pear-shaped, oval, circular, or irregular—in general contour; this being fixed upon, a pencil mark should be made on a suitable piece of cardboard or thin sheet zinc, defining the shape, but much smaller, say half the size of the intended vignette, and at, say, an inch outside this draw another, then cut out an opening with the smallest line for the boundary, and from the edges of this to the outside line make a regular series of sloping cuts about three-sixteenths of an inch apart, and the strips thus left may by another cut in the opposite slope be made into pointed teeth—the fineness of the teeth and their length will determine the gradation of the vignette. It will be necessary to also make some of these serrated screens with short teeth in order to work with negatives that have very narrow margins or rather space between the figures and edge of plate. The greater the space in moderation of background at disposal the more easy vignetting becomes, and *vice versa*. This, I believe, is accepted as the best method in vogue of vignetting ordinary portraits by all those who aspire to the production of artistic work. There are many other ways and means of softening the edges, but all give more trouble and produce no better results.

The well-known vignetting glass, which is a piece of flashed ruby or orange glass with the colour ground off the central portion in an oval or pear-shaped form, or a lithographed tint, or series of tints, on tracing paper, leaving the centre clear, or a negative of a large black and white shaded screen of suitable design, or a screen made of different thicknesses of tracing paper overlapping at their edges; but with all these plans the *shape* is *definite*, and cannot be modified to suit the negative under treatment, and a little alteration in this respect is often all the difference between a satisfactory and unsatisfactory form. At one time vignetting by the aid of cotton wool tucked under a paper mask and graduated by being pulled out in

a greater or less degree was the chief method adopted. Even now with some pictures this plan is not to be despised, but for ordinary work it is too troublesome and uncertain, and the results are not satisfactory in proportion to the care and adjustment required. A simple hole in a card laid over the print and placed on a revolving table has its advocates, but scarcely commends itself if any number of frames have to be attended to.

When the vignetting by any plan is required to reach nearly the edge of the negative, a roughly shaped mask of thin opaque paper should be laid on the face of the negative in addition to the vignetting arrangement paper on the back, in order to prevent lines showing from the lateral penetration of the light through the edges of the negative, which would quite spoil the vignette effect; it is also a good plan to paint the edges of the negative with black varnish. A plan sometimes adopted is to stipple the back of the negative with opaque colour applied with the fingers, but this is more useful in fancy than in plain vignetting, where the idea is to get the most delicate possible graduation of the image into the plain background.

So far suitable negatives have been treated upon, but there remains a large contingent of most unsuitable ones that as a matter of business have to be made the best of. We will give our attention to a few of the most usual ones. First, then, is the portrait with a dark background or surroundings. Now it is evident if we were to proceed as in the case of a suitable negative the result would be unsatisfactory, so to make the best of it a certain amount of work dependent on circumstances must be bestowed on the negative in order to make the background print lighter; stippling the back of the negative with opaque colour, graduating it close up to the face, is productive of a better effect than actually painting out the background or the face of it, for unless there is a little tint printing through the result looks hard and patchy; in fact, in the case of a painted out ground a tint should be introduced by covering the figure with a mask and letting the light act through it until the desired gradations are attained. If the original background is abruptly dark and light, the first thing to do is to stipple the transparent parts up to the average printing density of the opaque ones for a little space round the figure, and then vignette in the usual way. This may occur when one portrait is required from a group, or if the background represent an interior, &c.; in any case it facilitates matters to equalise the grounding. The most difficult part is to graduate off an unsuitable ground when the figure is profile, and the hair is loose and tumbled, without either interfering with the likeness or producing a blotchy effect. It can be done by the methods already described, but great care and work both on the back and front of the negative is required.

In vignetting a landscape there is very little trouble. The form being decided upon, it sometimes happens that the branch of a tree or something or other prints too strongly into the vignettied portion; in that case paint over the too dark parts on the back of the negative with a wash of gamboge yellow, which will remedy the fault. Of late years it has been a favourite way of illustrating books by adopting a semi-vignette form of illustration; that is, one part of the subject bounded by a sharp line, and the other graduated. This mode is somewhat difficult to manage nicely, principally for the reason so few negatives, unless taken expressly for the purpose, lend themselves kindly to the treatment.

To begin with, the negative should be twice the size of the print required to get a good result. To produce a dark line round the portion selected the face of the negative should be covered with a clear piece of *papier minérale*, a line drawn of the required form in reverse, the outside of it being rendered opaque with colour; this is necessary to obtain a sharp line, as if it was drawn on the back of the glass it would be more or less blurred. The stopping out, which can be done with indian ink, will have to be continued amongst the foliage on the upper side of the negative so that a judicious portion of it is left, then the lower part of the negative is vignettied in the usual way. As this kind of vignetting depends for its beauty entirely on the skill of the operator, it is impossible to do more than indicate the method of procedure, as each different view might be best with some little variety of treatment in either stopping out or graduating, a suitable negative being available. Of all kinds of landscape vignettes these seem to me to be the most charming.

EDWARD DENMORE.

INSTANTANEOUS WORK.

XI.

It frequently happens that when working in the vicinity of a farmyard some nice pictures may be got of cattle lying down in full contentment, chewing the cud. Should the locality be a quiet one,

and the animal of a restful disposition, there will be little difficulty in getting sufficiently near with the camera to ensure a tolerably fair size of figure on the plate, but even here it is better to arrange the focus beforehand, and judge of the distance when approaching them. When taking, say, cows of a dark brown colour, it must be borne in mind that such will stand a considerable amount of exposure, and one very important point to observe is the taking of them from the sunny side. In my opinion, when photographing a dark brown cow with a shutter exposure, a lens of large angular aperture is needed, and I know of a very clever operator who uses, with marked success, a portrait combination for such. I have also got good results working with a rapid symmetrical at something under $\frac{1}{4}$. Such is just a case in point where the operator must bear in mind that the colour of the object being photographed has a considerable influence on the results, and such should only be attempted under the most favourable conditions of light. I know that many people have an inward feeling of distrust when meeting, or approaching cattle in any way, and would rather dispense with such subjects in their travels with the camera. It is wonderful, however, what a little intercourse in farm circles will do in the way of dispelling any inward fear that may arise when going in and out among the cattle. As a rule, when a herd of cows are seen to be lying down in a contented manner, chewing the cud, no fear need be entertained of their doing any mischief. I have seen my little boy approach some of such, and coolly clap them with his hands, and my little daughter, of three years old, used to make a point regularly of feeding some very wild-looking highland storks with cabbage leaves out of her own little baby hands across the fence, until, after a time, the storks came to look for their little girl, and always came to her when she called, "Coopie, coopie!" Then was my opportunity to get cattle subjects. Any one who is desirous of getting along well with cattle must, at the outset, banish all thoughts of danger, and have no fear to approach and go in and out among them.

An enthusiastic photographer need never be short of subjects at a farmyard, even in winter as well as in summer.

There are, however, many other places—when considering inland work—besides a farmyard, and which offer excellent opportunities for some pictures to be got with the camera. Near most large towns is to be found a canal, and on the banks or water of such there is always to be found something worthy of a plate. I don't know if all canals offer such specially fine subjects as I have met in with on the Forth and Clyde, but on this, at certain times of the year, are to be found some delightful pictures of fishing boats sailing merrily along. In the spring of the year large numbers of east coast fishing boats proceed to the West Highlands to the herring fishing, and as they study economy and dispense with tracking, they are to be met in with in large numbers, sailing from east to west; and a very delightful picture such makes, with their dark brown sails extended as they skim along the smooth surface of the water. But whatever canal it be, there are always plenty of subjects for the camera, and a day spent on the banks at some nice picturesque spot makes a very pleasant outing. I have seen a very pretty picture knocked out of a couple of gray horses dragging a timber log. White or gray horses come out best, and they are easily secured by fixing on a spot beforehand for the focus, and when they arrive at the exact place chosen let off the shutter.

One of the best bathing pictures I ever met in with was got on the banks of a canal, for in summer time urchins will have a duck, and are not over-particular about the water they swim in.

There is plenty of good things to be picked up on the banks of a busy canal by the exercise of a little patient waiting.

But some may say they don't want to tramp so far for inland pictures. Then, in such a case, let him turn to and see what he can get almost at his own door. Many a day, when not in a photographic mood, have I been struck with what I have noticed at my own doors, as it were, and wished I had my camera ready.

What town is there in the suburbs of which some enterprising Punch-and-Judy man does not turn up at now and again? Very likely at first such may be of an evening, for the artist knows well the best time to visit, so as to catch a full audience of youngsters; but a quiet shilling, judiciously administered, will bring the proprietor round next Saturday at three o'clock, if fine; and what a charming picture such makes! Nor need the youngsters know anything about the photographic part of the entertainment, for the little undertaking is very easily performed from one of your windows without in any way attracting the attention of the delighted audience, with their gaping mouths and merry eyes. A little previous arrangement with the proprietor will enable the show to be set up just on the most desirable spot for the light at the time chosen for the entertainment.

Then, again, in many poor neighbourhoods there is always to be found a candy man, and even such with his wheelbarrow makes a

good picture, if you can just catch some ragged little urchin busy at his little game of barter. I was once a spectator, at a country inn, of a delightful picture of this kind, and I mean to have it out yet, even should I have to get up the show; but such are best taken without any pre-arrangement, for then you get everything more natural.

I wonder where, also, is the locality that some little youngsters are not to be found playing at shop; or little lassies amusing themselves with a skipping rope? I have had my turn at the latter, and failed over and over again; but at last I succeeded. It is one of the most difficult subjects I know of in photography, and requires a very fast exposure and rapid plate to secure a sharp picture. I tried several times before I succeeded, at last, however, by choosing a spot which gave me a dark background, and by giving the skipping rope a good rubbings with whiting, I got a good result. There is just a knack in catching the rope at a certain height, and it should be taken full on—not sideways, and if the exact moment can be seized when the little jumper is off the ground, it makes the effect more real. I was once told that my picture was dodged up, and that it was not a rope at all, but a white wand which the little girl was using and posing over her head. Such, however, was not the case, and so I brought my unbelieving friend out, and let him see how it was done; only this time I got a number of little lassies, and two of them to "caw." Such a picture can only be done in the very best light and with the shutter going it on a lens working about f .

Another very common picture to be met with in nearly every locality, but which, when a little pains be taken, makes a nice photograph, is that of a few little urchins playing at "moshey." Over and over again I have stood and watched them at this game. Unlike the skipping rope, a full exposure can easily be given on such a picture.

But, after all, I think the prettiest subject I ever saw for an instantaneous picture was a group of three little children sitting on a doorstep, with a broken bowl and clay pipes, delighting themselves to their hearts' content in blowing bubbles. So much was I struck with this sight that it was not long before I got some little models rigged up with pipes and soapy supplies. At first, however, I could not get the little ones to give me the same delightful expression on their faces which came so naturally to the first group I met. They knew they were being photographed, and hence got into a stiff and somewhat forced pose. I, therefore, just let them alone to their own sweet will for about ten minutes; they very soon entered into the spirit of the amusement, and I saw gradually appearing the same childish delight in their little faces as I had witnessed in the first group. I then quietly began to hum to myself a little tune and set my camera up all right. Sitting down not far from them, with the ball in my hand, they did not know they were just about being taken, and so waiting till a "fine one" was nicely poised, and a pair of wicked, large, dark eyes were just beaming with excitement at the glorious colours, I seized my opportunity and exposed.

In taking such a scene as this, the little ones are best left to themselves; the moment any one attempts to pose them in some particular place or way, so surely will they lose that grace and naturalness, which, to my mind, makes the little group so charming. Of course they have an idea, in fact know they are being photographed; but after a minute or two they lose the stiffness and drop into their own little graceful ways.

Such are among a few of the many little opportunities that are offered to an enthusiastic worker even in the vicinity of his own doorstep. There are many others, "which, when found, make a note on."

Not very long ago I met a friend who had gone almost mad to get a picture of sea gulls. He had seen the photograph of these birds which was so kindly distributed to the members of the Convention at the Glasgow meeting, and was so struck with the different shapes and appearances which the birds assume when in a flock, that nothing would do but he must have a shy at them himself. When I first met him he had been inquiring in all directions as to where was the best place to get a chance at the gulls, until at last, acting on the advice which some one had given him, he had made up his mind to proceed to "Ailsa Craig," and then get among the innumerable flocks which make this island their abode. On my telling him he "needna gang see far," he seemed quite astonished. His idea was to charter a small yacht and go for a week's sail, and so visit this secluded spot; but on my telling him to go on board the *Columbia* some fine day, and fire away from the promenade deck there, he seemed quite crestfallen, for he had, by some means or other, come to consider the photographing of gulls as one of the most difficult of operations, and which was only possible on some secluded island, under circumstances of great difficulty. But what photographer has not been on the *Columbia*? Still there are many, I have no doubt, who have never had a shot at sea gulls.

From time to time I have fallen in with some people who have the

most strange ideas regarding instantaneous photography. I remember once, when staying at one of our hydropathic establishments, meeting in with a masher and his sweetheart who were big on photographing a running fountain, which looked so charming in the grounds, backed up as it was by the dark green foliage which surrounded it, and so one day they told me they had been having a try, but that somehow the plates were bad, for they could get hardly a picture at all. I asked the lady what exposure she had given. "Oh, I made my Newman's shutter go pretty fast, don't you know, just to catch those delightful sprays; but I fancy I shall try it a little quicker next time," she said. I made no reply, but at once said to myself, "It's not much this pair know about photography;" so I persuaded the young gentleman just to lend me his camera while he went to town next day. So the morning being very fine, I quietly went out to the fountain and at once saw it was not a subject for instantaneous work at all. Getting a few friends just to stand still while I took off the cap, I gave forty seconds' exposure, with a stop of about $\frac{1}{32}$, and quietly huddled up and walked off to develop. It turned out a beauty; every jet of water showing up just properly. So after dinner time I showed the negative to both the lady and her friend, and they said, "By jove! just see how the spray and jets come out! That must have been taken far faster than we did it, Arthur!" and so they there and then determined to have another try. When, after repeated trials, they gave it up, I told them they ought to have given forty-five seconds, with $\frac{1}{32}$, they stood amazed. "But how can you get the water sharp?" they said. "Never mind the water," I replied; "you expose for the dark green shrubbery, and you will be just about right for the fountain."

Now this is a very common error with a great number of beginners. They have an idea that a small waterfall in some charming secluded glen must be taken with a shutter "*because the water is moving.*" Now, this is a fatal mistake. If you want a picture, you must expose for the darkest part of the glen—never mind the moving or flowing water, it will take care of itself; and when you come to develop, if proper precautions be taken, it will be found that the water is quite natural, and as it should be.

T. N. ARMSTRONG.

PHOTO-MECHANICAL JOTTINGS.

WHEN working photo-litho or photo-zinco on a commercial scale the wet collodion process is the most suitable, both on the ground of economy and efficiency; and when the wet plate bath is kept in constant use and at its proper strength the process is simple and certain, and, except in very dull weather, is quite rapid enough. But when the process is only occasionally in use, and at rather long intervals, then the silver bath is very uncertain in working. The temperature of the dark room also has a good deal to do with certain results, so, taken altogether, the wet collodion process is too erratic for those who require only an occasional negative for a photo-litho transfer, or a print on zinc for etching. It is this class of worker who is the most benefited by the recent introduction of photo-mechanical dry plates, and by substituting them for the old wet process are enabled to do their work with certainty and comfort, more especially if hydroquinone be the developer used.

Pyrogallol can be used, and yields good results, with a little more trouble entailed by the necessity of using a clearing bath of alum and acid. The great secret of making good negatives on these plates lies in giving full exposure in the camera, using a full dose of bromide in the developer, and by taking plenty of time over the operation.

Ammonia, or the carbonates of soda and potash, may be used with the pyrogallol, the best preservative being the meta-bisulphite of potash. One of the fallacies with regard to these negatives is that extreme density is absolutely necessary. This is wrong, the golden rule being—get clear lines; density—i.e., extreme density—is not required. A finished negative to be good must, when laid upon a piece of white paper, show each and every line clear, and quite free from even the slightest veil.

Negatives for collotypes, or for half tone photo-lithos, are of a totally distinct class, the collotype requiring a good soft negative, suitable for silver printing; half tone photo-litho, on the other hand, a negative well exposed, but too flat for silver work, as unless the light can get through the negative there will be no reticulation of the gelatine, whether from paper or a collotype plate. Negatives for collotype printing must be what is usually called reversed, and if they are to be made specially for the process should be made with a plane mirror, in which case they will be right for the process. Stripping and flexible films also give negatives suitable for collotype if developed without stain, as stained negatives are peculiarly unsuitable for collotype exposures. Negatives taken in the ordinary

way may be made available for collotype, either by stripping or by reproduction.

To strip a gelatine negative, first clean the back thoroughly, then carefully level upon a levelling stand. Now coat with as much plain collodion as can be put upon it without running off; do not run any of it off, as the object is to get a thick film of collodion when set so that the stripped gelatine film may be easily handled and be without risk of stretching. The negative coated with collodion is allowed to remain upon the levelling stand until the film of collodion is perfectly set, when the plate is immersed in a dish of clean cold water, where it must remain until the whole of the alcohol is washed out, this being indicated by the absence of any apparent greasiness of the film. Now immerse in a dish containing a mixture of water eighty parts, hydrofluoric acid one part, rock the dish gently until the edges and corners of film show signs of leaving the glass, then remove the plate from the dish and wash well under the tap, washing both back and front. Then, having placed a plate previously cleaned and coated with gelatine one hundred and fifty grains, chrome alum five grains, water twenty ounces, dissolve and filter. Plates coated with the above should be prepared beforehand, as they improve by keeping. The negative, ready for stripping, is now held film down upon top of water, when the film will leave the glass and float upon the surface. Now carefully adjust in position upon the gelatinized glass and lift out of the water, and with a soft, short squeegee drive all water from between film and glass. Now soak in clean methylated spirits of wine for five minutes, then place on a rack to dry. This method of stripping is perfectly safe and certain, if there is a thick enough film of collodion which has been allowed to properly set before washing. Negatives that it is not desirable to strip must be reproduced, and the best way to do this will be to first make a transparency in carbon, and from this make the reversed negative either the same size, or larger or smaller as may be desired. If the negative is to be the same size as the original, the best way to make a reversed negative—after well cleaning the back of transparency—is to place it in the carrier of dark slide film up, then dust the film and place a dry plate in contact with the transparency, the slide is now closed and removed to the studio. Now place in front of the camera a large sheet of white paper in such a position that it reflects quite evenly into the camera. Adjust the camera as far away from the sheet as possible, so that the whole of focussing screen is illuminated. Now adjust the lens so that the reflector is perfectly out of focus. Then insert the dark slide containing the transparency and sensitive dry plate, draw up the shutter, uncup the lens, and make the exposure, which will range from five seconds to one minute. The after operations are those usual to the development of a negative. This plan of exposing in the camera will be found to yield far the best results for making contact negatives from carbon transparencies. There are two advantages in using carbon transparencies for the reproduction of negatives: one being their acknowledged superiority over any other transparency for the purpose; the other, they are the only kind that will allow reversed negatives to be made by contact.

If the negative for collotype is required either larger or smaller than the original, the transparency is placed in the enlarging camera, film inwards, and the negative made therefrom the desired size.

W. T. WILKINSON.

[The next "Jottings" will be the various methods of making photolitho transfers in line and half tone, and the preparation of collotype plates.]

COLLODIO-BROMIDE EMULSIONS.

[A Communication to the Society of Amateur Photographers of New York.]

In bringing this subject to your attention, I am reminded of the fact that it is nearly ten years since I had the pleasure of experimenting with collodio-bromide emulsions—not so much in manufacturing them as in using those put on the market at that time, made after the formula of Mr. Henry J. Newton. We then had to prepare our own dry plates and give a considerably longer exposure than is now necessary, but we had the satisfaction of obtaining beautifully clear, crisp, and dense negatives. There was more latitude in exposure and development than now.

Considerable attention has been given of late to lantern slide making, and as a few of our members have had difficulty in obtaining good slides on the special gelatine lantern commercial plates, owing to a loss of sensitiveness or foginess and flatness, which does not fully show itself until after the plate is fixed, it occurred to me it might be useful to explain a few formulae for making and using collodio-bromide emulsions, for the reason that they are rather more convenient for the amateur than the use of the ordinary wet plate collodion process, since the use of the silver bath is avoided, and beautiful crisp slides, full of clear, bright lights, are readily obtained.

In making lantern slides a slow washed collodio-bromide emulsion is

preferable; one to be had ready prepared, that gives fine results, is made by Mr. William Brooks, of Reigate, London, and it is what I have been lately experimenting with. The formula for making the emulsion was given by Mr. Brooks to Mr. Frederick Dunsterville, of Rayapuram, Madras, and what follows will be a description taken from Mr. Brooks's and Mr. Dunsterville's directions.

Prepare three separate solutions, in ordinary daylight, as follows:—

PLAIN COLLODION.

Alcohol, methylated	4½ drachms.
Ether	3½ "
Gun cotton, high temperature.....	12 grains.

BROMIDE SOLUTION.

Alcohol, methylated	1½ drachms.
Ammonium bromide	13 grains.
Distilled water	20 minims.

SILVER SOLUTION.

Silver nitrate.....	20 grains.
Distilled water	12 minims.

The most important feature of these solutions is the employment of a suitable kind of pyroxyline or cotton (in this country Hance's is considered the best), then the process is comparatively easy and certain. Make a stock of plain collodion and let it rest for some time, so that all insoluble particles and other impurities may sink to the bottom. Tall, narrow bottles are best to store it in. The proportion for a stock solution may be:—

Alcohol	22 ounces.
Ether	18 "
Gun cotton, high temperature.....	1 ounce.

Referring to the three solutions above mentioned, the bromide should be made by first dissolving the bromide of ammonium in the given quantity of water, heated to near the boiling point; then when cooled to 70° Fahr. the alcohol is added. The water of the silver solution should also be warmed to dissolve the silver easily and rapidly.

To make the emulsion, pour one ounce of the prepared plain collodion into a clean four-ounce bottle with glass stopper, then add the bromide solution as previously given, shaking well for some minutes. The bottle containing the bromized collodion should then be taken to the dark room, and the silver solution added little by little, shaking well between each addition. It is well to rinse out both the bromide and silver bottles with a little of the collodion to ensure the whole of the salts being taken up. The emulsion should then be kept in the dark room for about twenty-four hours, shaking well at frequent intervals, and when ready for washing it should be poured into a glass dish, which should be large enough to contain the quantity of emulsion in a mass not thicker than one-eighth of an inch. As the solvents evaporate a skin forms on the surface, which should be broken up occasionally with a silver spoon or ivory paper-knife. When the solvents are completely evaporated the pellicle should be washed in distilled water for half an hour or so, until all the soluble salts have been removed.

The pellicle should then be squeezed in pieces of clean calico until as much as possible of the water is removed, and it can then be dried by moderate heat over a water bath. The whole of the washing process should be done in a dark room, or at night-time by the light of a candle placed at some distance.

When quite dry the pellicle may be redissolved in three-quarters of an ounce of absolute alcohol (0·805) and three-quarters of an ounce of sulphuric ether, pure (0·720), pouring the ether on first; and when all the pellicle is dissolved, the bottle (a four-ounce one) should be well shaken up, and in about twenty minutes to half an hour will be ready to coat plates, after being filtered. It will be a milky coloured solution, resembling somewhat cream in consistency.

The filter for the emulsion may be merely a small funnel with a little tuft of cotton jammed in it, through which a little alcohol should first be run, or, what is better, the first portion of emulsion running through may be returned to the filter. A friend of mine, Mr. A. S. Murray, advises the use of paper filters instead of cotton, for he found particles of the cotton would find their way into the emulsion and cause specks on the plate.

Before coating a large number of plates it is advisable to test the emulsion in the dark room, to see that it is free from fog, by coating a plate; as soon as the film is set wash it in clean water by soaking until all the ether and alcohol are removed, which will be observed as soon as the greasy lines disappear. Then pour over the plate a little developer of full strength, and after letting it remain on the plate for a few minutes wash well and fix with a solution of cyanide of potassium. It should be absolutely free from fog and stains. Stains may be due to the plates not being chemically cleaned; but if fog is present a drop or two of an alcoholic solution of iodine added to the emulsion will effect a speedy cure. The emulsion must then be well shaken up again and allowed to rest half an hour before retiltering and coating plates.

Having thus prepared the emulsion, or purchased it already made, the next step is to coat the plates. These must, however, be first cleaned and prepared with a substratum, or edged with a rubber solution or some

other substitute to hold the film firmly on to the glass. Mr. Dunsterville recommends soaking them in a dilute nitric acid solution (acid one part, water ten parts), then rinse them in plenty of clean water, drying them with a clean cloth. They should then be polished on both sides with a cleaning solution (say tripoli powder mixed with methylated alcohol and a little ammonia), care being taken to wipe off the edges that were clamped in the vice with a clean cloth. They should then be either edged all the way around one-eighth of an inch wide with a rubber solution, or they may be dipped in a hot solution of gelatine (twenty grains to twenty ounces of water), and dried with a clean cloth.

Mr. Brooks advises that the plate be cleaned with a piece of clean rag, moistened with methylated alcohol, and polished with a clean chamois leather, kept for the purpose only. No substratum is recommended. He says, after cleaning the plate, holding it on a pneumatic holder, edge it with a rubber solution (this is to prevent the film from slipping during the after manipulation). The solution is best applied with a camel's hair brush cut down almost to a stump, with a piece of wire or a slip of glass tied on the side projecting below about one-eighth of an inch, to act as guide. I followed this method of cleaning, purchasing some new glass. I soaked it in nitric acid and water, then washed it and cleaned by placing the plate in an ordinary wood screw vice, pouring on a little alcohol, and polishing with soft paper called *Papier Joseph*. I then give it an edging of the Eastman rubber solution and coated the plate with the sensitive emulsion.

During the development the film loosened from the glass and became entirely detached, which I could not save. The balance of the plates thus coated I edged with the rubber solution a second time, and these films in most cases stood the development and fixing without coming off. Some would loosen slightly at the corners where the edging had not adhered sufficiently. So far, then, as Mr. Brooks's directions relate to the preparation of the plate, they are insufficient, for it is evident the collodion film will not adhere unless the edging solution is applied before and after coating. It was formerly my practice to first flow a substratum of albumen over the plate, then dry, and afterwards flow the collodion; then the film would adhere perfectly. This, I am informed, is now the general practice in the preparation of wet plates.

Mr. Murray informed me that he prepared a solution of albumen by beating up the white of an egg with an egg beater, then allowing it to settle for twenty minutes, and rebeating a second time. It is then filtered through a paper filter, a drop or two of ammonia added, and is ready for use. A glass plate that has been well soaked is washed off under the tap slightly and drained. The albumen solution is poured on at one end and gradually flowed towards the other, driving what water there is on the plate before it. The surplus is drained off into the bottle. The plate is set up in a rack to dry. After this it is coated with the emulsion, and when again dry is edged with the rubber solution. Thus there is no chance for the film to slip. Several plates may be quickly albumenised and kept ready for use in a grooved box, free from dust. Then, when it is desired to prepare plates, they have only to be coated with the emulsion and edged with the rubber solution, which takes very little time; a dozen can easily be coated in twenty minutes.

Dr. J. J. Higgins recommends the use of gum tala as an edging solution in place of rubber; it can be obtained at any drug store.

F. C. BEACH.

(To be continued.)

THE CATALYSIS OF POTASSIUM CHLORATE AND MANGANESE DIOXIDE.

Reactive the action of heat upon potassium chlorate, either alone or when aided by the addition of manganese dioxide, so well known is the decomposition that to attempt a more explicit explanation than is afforded by the numerous text-books of science would present a grave difficulty. But, as regards the addition of manganese dioxide, when we enumerate the various hypothetical reasons that are assigned to its use, and the replacement of the same by such absurd bodies as sand, &c., even by those who are supposed to hold high stations in the chemical profession, it can be readily understood that their general mode of reasoning must either be of an alchemical or an extremely orthodox type. True, to speak definitely of such a reaction would be extremely precarious, owing chiefly to the instability of the salt under question when exposed to an elevated temperature, and also to the peculiarity of the decomposition of the same, namely, the formation of a chloride, which, in its turn, either vigorously attacks, by the formation of secondary reactions, or totally destroys or contaminates the would-be products.

Evidently the surmise that manganese dioxide is attended by surface action, which is referred to by several authors, would, to any practitioner, be difficult to endorse, since the same portion, after separation by lixiviation, even to an indefinite number of times, is as active as in the first instance; but such cannot be said of surface actions in general, in which may be mentioned the case of finely divided platinum, which speedily becomes impaired.

Although manganese dioxide is not the only substance that promotes the evolution of oxygen from potassium chlorate, yet, among those substances that are influential, all are observed to bear a similar ratio to one

another; such, for instance, as cupric and plumbic oxide an unstable sesquioxide of copper appears to exist. Oxide of copper has, therefore, a feeble affinity for oxygen, and though that affinity is not sufficiently adequate to retain the oxygen when separated from the potassium chlorate, it may undoubtedly aid in effecting its liberation. Sesquioxide of iron is also susceptible in the ferric acid of a higher, but unstable stage of oxidation, and the same holds good of oxide of lead; hence their compounds facilitate the decomposition of the chlorate.

There is at present no proof of the existence of a higher oxide, either of zinc or of magnesia, and in accordance with the same, no perceptible effect is produced by the introduction of these compounds in place of manganese dioxide. This also would remove doubt why powdered glass and sand are as equally inert. It is also not improbable that, during the decomposition of potassium chlorate, minute traces of manganates may be produced, since the oxygen thus obtained is always contaminated with small quantities of free chlorine.

A somewhat striking experiment in favour of this may be performed as follows:—An intimate mixture of the two compounds is obtained and introduced into a wrought-iron tube closed at one end, the further extremity being provided with a stop-cock or tap. The tube is now raised as rapidly as possible to a heat just below redness. Owing to the increased pressure exerted by the confined gas, the decomposition is much retarded. On a sudden liberation of the gas being allowed it naturally escapes with great violence, and invariably carries with it a large supply of chlorine gas. The contents of the tube also produce, on examination, proofs of distinct traces of free alkali.

—Chemical News.

H. N. WARREN, *Research Analyst*.

KEIGHLEY PHOTOGRAPHIC EXHIBITION.

The authorities of the Keighley Mechanics' Institute, under whose auspices the Exhibition which was opened on Tuesday last is held, are sincerely to be congratulated on the success which has rewarded their enterprise. Taking into consideration that it is the first exhibition of the kind that has been held in the town the result is most creditable. The claim made in the local advertisements that it is the most important exhibition of the kind ever held in the north of England is, of course, an extravagant one, but the efforts of those who have taken the matter in hand, and the liberality of their offers of prizes, have resulted in bringing together a collection of about 400 exhibits, in which are included a large proportion of works of well-recognised merit, while the amount of rubbish is not great. The average is a very fair one.

The shortcomings in matters of detail in the arrangements are not few, and for some cases nothing short of extreme carelessness can account; but, on the other hand, there are many points open to adverse criticism for which much may be urged in extenuation. It is to be hoped that this is the first of a series of annual exhibitions, and that the experience here gained will bear fruit in the future.

It is to be noticed that an appeal is made in the catalogue to the amateur photographers of the town and neighbourhood to form a Society, the Council of the Institute promising to assist in any movement with this object. It would be a matter to be regretted if this opportunity were not taken, as the amount of work sent in from the locality is far less than should be the case, and that, with a few noticeable exceptions, is not up to average merit. A local Society would no doubt assist in mending matters in this direction, but at the present day, when the spirit of the times is against drawing a distinctive line between the amateur and the professional, and in favour of judging each man's work according to its own merits and without reference to his personal position, is it advisable to make it an *amateur* Society? In this connexion it may be mentioned that several exhibitors in the amateur classes quote a price for their pictures in the catalogue.

The Exhibition will be open every evening this week, and a further extension of time is under consideration. As there is ample accommodation, one source of discontent—that of unfavourable hanging—is reduced to a minimum. The pictures, &c., are grouped in their several classes, with a few perplexing exceptions, and a praiseworthy attempt has been made to assist comparison; this attempt has been somewhat interfered with by the eccentricities of the catalogue, but most of the failures in this direction are obviously due to want of experience, and will no doubt be remedied on subsequent occasions.

There are nineteen classes, of which five are open to professionals only. The judges were Mr. C. W. Hastings, of London, and Mr. Stevenson, Art Master, of Leeds.

Class I. *Landscape or Seascape*. Professional.—H. P. Robinson takes the silver medal with *A Lobster Boat: Early Morning*; the bronze medal is awarded to E. Greaves's *On the Heben*—a charming study of wood and water. In this the foliage is rendered with a truth as regards tone too rarely found. F. M. Sutcliffe obtains a certificate for one of a series of five studies, all of which are worthy of his name; one of these is attributed in the catalogue to M. Auty, who sends six examples of somewhat unequal merit.

Class II. *Pictures*. Professional.—W. W. Winter's *Perplexed* obtains the first award; F. M. Sutcliffe takes second place with *The Daughter-in-Law*, which, although a meritorious work, is not altogether so pleasing

as some of the productions of this artist. A certificate is given to Mr. and Mrs. Anckorn for *The Charmed Ring*, which is not a particularly pleasing work. The effect is spoiled by a stiffness in the attitudes of the figures, and the composition of the picture is not beyond criticism.

Class III. Enlargements. Professional.—The silver medal falls to T. G. Whaitte for *Market Women, Normandy*, a picture glowing with sunshine. The bronze medal is awarded to M. Anty for *A Bit of Old Newcastle*, a most pleasing picture, strong yet delicate and full of detail, reminding one strongly of the same, or a nearly similar subject, by Lyddell Sawyer in the last Pall Mall Exhibition. *The Crypt, Wingfield Manor*, by T. Scotton, for which a certificate is awarded, is a difficult subject well treated.

Class IV. Portraits. Professional.—Messrs. Byrne & Co. take the first place in a small class of three competitors, T. G. Whaitte taking the bronze medal.

Class V. Lantern Slides. Professional.—The Woodbury Company are *facile princeps*, and obtain a silver medal. Messrs. Riley Brothers' collection of forty-eight slides are good but somewhat unequal. Messrs. Fry & Co. obtain a certificate. In this class there are also only three competitors.

Class VI. Landscape and Seascape. Amateur.—This is the largest class in the Exhibition, comprising as nearly as possible one-half the whole number of the exhibits. The first prize falls to J. E. Austin for *A Peaceful Scene*. This picture represents a country lane with a brook near the foreground crossed by a bridge, which must be familiar to those who are acquainted with Mr. J. Gale's works—in fact, it might be easily mistaken for Mr. Gale's well-known picture. Mr. Austin's other exhibits, however, show that his success is not a mere accidental one. G. Davison is well represented in this class, in which he takes a well-deserved bronze medal for *The Fishing Fleet*. W. G. Brewis's series of landscapes, for which he receives a certificate, show careful manipulation; they are, however, marred by having blank white skies. The same applies, but in a less degree, to a series by F. Illingworth. H. Forsyth's *Rustic Corner*, for which a certificate is awarded, is somewhat weak; a better print might possibly be made. The Rev. H. B. Hare well deserves the certificate he has obtained. A. Keighley, a local amateur, deserves some praise for his exhibits, in which there is evidence of considerable artistic perception. The red colour adopted in some cases does not appear the most suitable tint; *A Cooling Stream*, for instance, should look cool. E. Cowper's series are good examples of landscape work, and the work of W. Mitchell and A. Haggas, both local amateurs, deserves remark, although it is not of conspicuous merit.

Class VII. Pictures. Amateur.—A. Tagliaferro takes a silver medal for *Ave Maria*, which we cannot think altogether a pleasing picture. *A Berkshire Backyard*, by J. E. Austin, is quaint and interesting. A. Keighley's exhibits are particularly good, that is to say the prints from the original negatives are, especially *Gathering Water Lilies*; the enlargements exhibited, however, lack the good qualities of the originals.

Class VIII. Architecture. Amateur.—The judges have justly withheld the awards. Yorkshire is so rich in old abbeys, and picturesque and quaint buildings, that there is some reason for surprise that the opportunities have not been made better use of.

Class IX. Enlargements (Amateur). is a good class. Perhaps the most noticeable are A. R. Dresser's enlargements from detective camera negatives.

Class X. Portraits. Amateur.—With the exception of the exhibits of Rev. F. C. Lambert and A. Keighley, both of whom show really fine studies, the competitors in this class fail to rise above the most ordinary difficulties.

Class XII. Mechanical.—This class has two competitors only, both of whom deserve their respective honours.

Class XIII. Champion.—This is a slightly disappointing class. There are twelve exhibitors only, and among the ordinary class there are many eligible works which we should have liked to have seen here.

AWARD OF PRIZES.

PROFESSIONAL.—Class I. *Landscape or Seascape*. Silver medal, H. P. Robinson; bronze medal, E. Greaves; certificate, F. Sutcliffe. Class II. *Picture*. Silver medal, W. W. Winter; bronze medal, F. Sutcliffe; certificate, Mr. and Mrs. Anckorn. Class III. *Direct Enlargements*. Silver medal, T. G. Whaitte; bronze medal, M. Anty; certificate, Thos. Scotton. Class IV. *Portraiture*. Silver medal, Byrne & Co.; bronze medal, T. G. Whaitte. Class V. *Lantern Slides*. Silver medal, Woodbury & Co.; bronze medal, Riley Brothers; certificate, Fry & Co.

AMATEUR.—Class VI. *Landscape and Seascape*. Silver medal, J. E. Austin; bronze medal, G. Davison; certificate, W. G. Brewis. H. Forsyth, Rev. H. B. Hare. Class VII. *Figure*. Silver medal, Tagliaferro; bronze medal, J. E. Austin; certificate, A. Keighley. Class VIII. *Architectural or Interiors*. Awards withheld. Class IX. *Enlargements*. Silver medal, A. Keighley; bronze medal, W. Jackson; certificate, A. R. Dresser. Class X. *Portraiture*. Bronze medal, Rev. F. C. Lambert; certificate, A. Keighley. Class XI. *Lantern Slides*. Silver medal, B. G. Wilkinson; bronze medal, J. W. Wade; certificate, A. R. Dresser. Class XII. *Mechanical*. Bronze medal and Mr. Sneed's prize, H. L., Pickles Greenwood; certificate, Thomas Scotton. Class XIII. *Champion*

(Pictures that have been awarded prizes at previous exhibitions). Silver medal, H. P. Robinson; bronze medal, F. Sutcliffe; certificate, Mr. and Mrs. Anckorn. Class XIV. Silver medal (given by Messrs. Mawson & Swan, Newcastle, for best series of pictures taken on their plates), W. Parry.

THE OLDHAM EXHIBITION.

BINGO in the neighbourhood of Oldham a few days since, I took the opportunity of visiting the photographic exhibition now being held in that town.

The exhibits it is not my desire to criticise, except to congratulate the Oldham Society on having brought together so many works of more than average excellence. The arrangements and the hanging of the pictures, however, seem to me to be a splendid example of what to avoid in their respective directions. There are, according to the catalogue, fourteen classes, but, except in those for lantern slides, in which confusion is impossible, no attempt has been made at grouping the exhibits belonging to each class, and as the pictures themselves bear no indication, nor does the catalogue give any, comparison is of course practically out of the question.

The positions given by those responsible for the hanging are at every exhibition, more or less, and perhaps in most cases unjustly, a subject for adverse criticism, and therefore, but for the fact that I am not an exhibitor, and am in no way interested in the exhibition except as one of the public, I should be very diffident in expressing any opinion. I am, however, treading on fairly safe ground in saying that if the success of an exhibition depended entirely on the hanging, this exhibition would have been a failure. As an instance, Mr. H. P. Robinson's *Caroling*, which, whatever may be its faults, at least merits a place where it can be seen, is so placed that it causes little surprise that the judges have passed it without notice. Horace Gridley's gem, *A Good Flask*, too, can only be seen by assuming an undignified position on the hands and knees.

On the evening of my visit there was a lantern exhibition, and I naturally expected to see examples of the best work of the locality. Judge my surprise and disappointment when I found the entertainment to consist of a series of commercial slides, such as may be borrowed from any optician at so much per night, with a reading from the book supplied with the same.

Oldham evidently wants the Rev. Mr. Lambert badly. A. MACKIN.

THE RICHMOND EXHIBITION.

THERE is only one bad thing connected with this Exhibition, which is that it remains open only one week, closing to-morrow. It is indeed one of the finest exhibitions of photographs that we have seen for some time.

It was opened on Tuesday by H.R.H. the Duchess of Teck, who seemed to take quite a lively interest in the various exhibits. It has not been promoted with any commercial object, as in the event of there being a surplus it will be equally divided between the Richmond Free Library and the Athletic Association. There is also a lantern entertainment (presided over by Mr. William Brooks) each afternoon and evening during the week. This has been highly successful, as under such management it could scarcely fail to be. The compendious and really well-got-up catalogue is sold for the low price of twopence.

Those who have visited any photographic exhibition of late years in any part of the United Kingdom will see on the walls and screens numerous pictures with which they have made acquaintance many times previously, for, so far as we remember at the present moment, the exhibitions of the Photographic Society of Great Britain are the only ones confined to original work.

Quite a number of medals have been awarded, these being altogether irrespective of whether or not similar awards have not been made to the same pictures many times previously, and even by judges composed of some of the same elements as the jurors in this instance.

The judges on this occasion were Messrs. James Sant, R.A., H. Moore, A.R.A., T. C. Hepworth, J. Traill Taylor, C. W. Hastings, Lionel Clark, Valentine Blanchard, S. B. Wollaston, C. Hussey, and W. L. Wyllie.

In Division A (Landscape or Seascape, or series of same, open to all exhibitors)—Silver medal to F. M. Sutcliffe for a series of his charming pictures, *Feeding Calves, Rising Mist, et seq.* Bronze medal to H. P. Robinson for his *Lobster Boat*.

Division B, Class 12, same as above, but for amateurs only—Silver medal, J. Gale, *Afternoon Rest*, and series. Bronze medal, G. Davison, *The Part of Day*.

Division A, Class 3 (Figure subjects or interior with figures, open to all exhibitors)—Silver medal, L. Sawyer, *Tam o' Shanter*. Bronze medal, W. Winter, *Perplexed*.

Division A, Class 9 (Best picture on Fry's plates)—Silver medal, T. G. Whaitte, *Let you a dollar you don't*.

Division A, Class 8 (Best enlargements on Morgan & Kidd's opal or paper)—Withheld.

Division B, Class 14 (Portraits, amateurs only)—Silver medal, Rev. F. C. Lambert, *Ageismos the Slave*. Bronze medal, D. de L. Cohen, *Portraits*.

Division B. Class 15 (Figure subjects or interior with figures)—Silver medal, D. Barnett, *The Village Apple Cart*. Bronze medal, Miss F. A. Harvey, *Studies of Stags*.

Division H. Class 16 (Architecture, amateurs only)—Silver medal, T. H. Morton, M.D. Bronze medal, withheld.

Division H. Class 13 (Landscape or seascape, amateurs only, half-plate or under)—Silver medal, F. P. Cembrano, *Landscape Studies*. Bronze medal, E. J. Bedford, *Horses at Plough*, and series.

Division H. Class 17 (Instantaneous landscape or seascape, amateurs only)—Silver medal, L. Melden, *Express Train* and others. Bronze medal, H. E. Allen, *Sunsets on Windermere*.

Division A. Class 11. Photographs taken with London Stereoscopic Company's apparatus.—No awards.

Division B. Class 20 (Views within three miles of Richmond)—Silver medal, H. Little, *Red and Fallow Deer*. Bronze medal, F. Crookes, *Winter-tide*.

Division A. Class 2 (Portraits, open to all)—Silver medal, W. Crooke, *W. E. Lockhart*. Bronze medal, Werner & Son, *Portrait of a Lady*.

Champion Division. Class 22 (Open to all)—Silver-gilt medal, F. Thurston, *A Misty Morning*. Silver medal, H. P. Robinson, *Caroling*. Bronze medal, W. J. Byrne, *F. Tolmache*.

Champion Division. Class 23 (Amateurs only)—Silver-gilt medal, H. D. Arnold, *Roman Wall at Burgh*. Silver medal, J. Gale, *Cornish Doorway*. Bronze medal, Surgeon-Major Mantell, M.D., *Bristol Floating Harbour*.

Division A. Class 4 (Architecture, open to all)—Silver medal, L. Sawyer, *In the Castle Garth, Newcastle*. Bronze medal, G. W. Wilson & Co., *Rosslyn Chapel*.

Division B. Class 21 (Amateur Photographer, for best Amateur work)—Silver medal, J. Gale, *Homestead from Plough*. Bronze medal, L. Melden, *A Series of Pictures*.

Much credit is due to Mr. Chancellor, Hon. Secretary, for the success of the exhibition.

APPARATUS AND APPLIANCES.

The following appears in the *Thames Valley Times* of Wednesday evening:—"Mr. Whipple had the arranging of an excellent collection of photographic apparatus and appliances, sent in by various firms, and embracing some of the latest novelties, as well as other inventions that are better known and have stood the test of time. A prominent position is occupied by the 'Optimus' enlarging lantern, given by Messrs. Perkin, Son, & Rayment, for the best series of lantern transparencies. Messrs. Sands & Hunter exhibit their Imperial and Exhibition cameras, and a patent time shutter, which can be set for any length of exposure. Various lenses, cameras, stands, &c., are shown by Messrs. Spicer Brothers, as well as specimen photographs taken on their sensitised paper. Messrs. J. F. Shew & Co. are large exhibitors, their stand displaying pocket and detective cameras, their Eclipse hand apparatus, and the Eclipse enlarging apparatus, besides various other appliances. An enlarging camera of imposing proportions is shown by Messrs. Marion & Co., compared with which, in point of size, is Dr. Krugener's patent book camera, resembling in appearance a small book, while McKellan's detective camera is also worthy of notice. Messrs. Taylor, Taylor, & Hobson show a variety of lenses, and Messrs. C. Bracher & Co. exhibit their metal dark slides. Mr. Henry Parker directs attention to his improved Victoria cameras, and a cheap form of detective camera. Mr. W. Tylar has an excellent 5l. outfit, besides compressed pulp trays (with names prominently attached so as to be visible in the dim light of the 'dark room'), patent plate lifters (by which the staining of the fingers with chemicals is avoided), and other useful items. Mr. Jonathan Fallowfield shows an excellent detective camera, enclosed in an innocent-looking black box with strap handle, which would never be likely to arouse the suspicion of a shy and involuntary sitter. The instantaneous shutters of the most approved construction shown by the same exhibitor are well worthy of attention, as well as another form of detective camera which fits under the waistcoat of the operator, all that is visible being a tiny lens made to resemble a waistcoat button. Here also is a well-conceived magnesium lamp for studio illumination, besides enlarging cameras, petroleum lamps, dark tents, &c. Messrs. Bourn Brothers, of Richmond, show various cameras by Lancaster & Son, the exquisite finish of which would delight the heart of the most fastidious of amateurs, as well as detective cameras, enlarging lanterns, negative boxes, draining racks, and in fact all that an amateur is likely to require. Messrs. Hiffe & Son exhibit their photographic publications, and Messrs. W. Watson & Sons have an attractive stand, their specialities including tourists' cameras, folding tripods, a detective camera with Eastman's roller and regulating shutter for different exposures, an improved dark slide, a handsome studio stand, and other exhibits. A developing port-manteau, arranged to contain a complete photographic outfit, is shown by Messrs. G. Houghton & Son, who also display a developing sink with cover, arranged to form a complete dark room, and a portable garden or lawn studio."

After the exhibition of lantern slides of Windsor Castle, &c., by Mr. W. Brooks on Tuesday afternoon, before H.R.H. Princess Mary, Duchess of Teck, H.R.H. the Duke of Teck, H.R.H. Princess Victoria, and

suite, Mr. Brooks obtained permission to take a group of the Royal party by the aid of F. W. Hart's patent flash-light lamp, and having borrowed a tourist camera and lens from the stand of Watson & Sons he took two successful pictures, a lantern slide being made from one, which will be shown on the screen every afternoon and evening during the Exhibition. The whole thing was conceived and plates exposed within ten minutes.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
January 14	North Middlesex Club	The Iron Room, Stroud Green.
" 15	North London	Myddelton Hall, Upper-st., Islington.
" 15	Glasgow & West of Scotland Am.	180, West Regent-street, Glasgow.
" 15	Bolton Club	The Studio, Chancery-lane, Bolton.
" 16	Bristol and W. of Eng. Amateur	Queen's Hotel, Clifton.
" 16	Bury	
" 16	Burnley and District	Mechanics' Institution.
" 16	Hyde	
" 16	Manchester Camera Club	Victoria Hotel.
" 16	Edinburgh Photo. Club	5, St. Andrew-square.
" 16	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 17	London and Provincial	Masons Hall Tavern, Basinghall-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. James Glaisher, F.R.S., President, occupied the chair.

The PRESIDENT, on behalf of himself and of the meeting, expressed pleasure at seeing Mr. Leon Warnerke in their midst once more, he having just returned after prolonged absence in Russia.

Mr. Frank Newlan exhibited a detective camera consisting chiefly of an angular vessel of tin; in the interior quarter-plates were arranged round the outside of a drum, and half a turn of a key on the outside of the apparatus would so turn the drum as to bring a fresh plate into the field of the lens; the apparatus would take six quarter-plates. He also exhibited a new view meter, consisting of two sets of cross wires, the one disposed vertically and the other horizontally; between them was a reflecting and slightly convex mirror placed at an angle of 45°, so that by looking down upon this finder and view meter, and making the two sets of wires coincide to the eye, any object could be accurately centred for the camera, and would be nearly as brilliantly illuminated in doing so as when looking at the object direct.

Mr. JOHN SPILLER remarked that it seemed to be an admirable instrument with distinct features of novelty. Would not the Metropolitan Police and foreign Custom House officers suspect it to be a dynamite case?

Mr. NEWLAN intended to enclose it in a light case so as to externally resemble other detective cameras.

Mr. J. G. B. WOLLASTON remarked that the drum might be made to hold more plates by making it to encircle the body like a belt.

The PRESIDENT said that, under the new rules, all the officers of the Society would retire at the next annual meeting, and that nominations for their successors must reach the Secretary, at 5A, Pall Mall East, not later than January 21 next. He then moved that Mr. W. E. Debenham and Mr. George Scamell be appointed Auditors.

This was agreed to.

The meeting then appointed as Scrutineers Messrs. T. Samuels, J. D. England, Friese Greene, Arnold Spiller, Charles Sawyer, George Scamell, W. Cobb, J. A. Harrison, and J. R. Gottz.

Mr. LEON WARNERKE, in response to an invitation from the President to give any news about photography in Russia, said that this was the Jubilee year of photography, fifty years having elapsed since Daguerre first made known his discovery to the French Academy; the Moscow Photographic Society, which was formed three years ago, had, therefore, resolved to celebrate the Jubilee by holding a photographic exhibition. Before he left Moscow everything connected with the coming exhibition promised well. It had been opened that very day, and he had just received the following telegram, which he would translate from the Russian language:—"Observing the Fiftieth Year, Jubilee of Photography.—The Committee appointed for the organization of the Exhibition, at the Comrades' Dinner, drink your health as the person to whom the Moscow Society is thankful for its existence: Entschewsky, Clugenau, Klatschke, Zirmen, Thiele, Lauine, Fischer, Reine, Eichenwald, Rodionoff, Nelline, Golitzin, Kneopp, Matterne." The Moscow Exhibition is a very large one, and patronised by influential people; it has excellent rooms in an enormous museum—a new one and quite a palace; the Society was allowed the use of the rooms on condition that it furnished and decorated them; this it agreed to do, and took fifteen rooms for the purpose. There is not much platinotype work in Russia; what is done is upon an experimental scale only, because the platinotype paper is made in England alone, and by the time it reaches Russia it is spoilt. The Moscow Exhibition is an "All Russians' Exhibition," and will be followed by others annually. He started a photographic exhibition in St. Petersburg last year, and invited about three hundred influential persons to be present at its opening. The Emperor said, "Why did you not invite me?" but it would not have been etiquette to have done so, so he said that he intended to come; he did so and brought all his family. He (Mr. Warnerke) started the St. Petersburg Exhibition because the photographic society there had not the courage to do it; it proved successful in every sense, even commercially, although they had been bound down to charge very low rates for admission; the overplus will go towards the expenses of this year's photographic exhibition at St. Petersburg, which will be international in character and held in April. Magnesium flash lights and detective cameras are coming into use in Russia.

The President having vacated the chair, Mr. W. S. BIRD stated that it is intended to have a public dinner of the members of the Society, and that those who wish to purchase tickets should write to Mr. W. England, 7, St. James's-square, W.

CAMERA CLUB.

On Thursday, January 3, a discussion on *Hydroquinone* was opened by the reading of a paper by Mr. T. CHARTERS WHITE. Sir George Prescott presided.

The lecturer referred to the chemical constitution of hydroquinone, and summed up the advantages which, in his opinion, were obtained from it as a developer. He also gave his experience with the several commercial samples obtainable, and handed round negatives of microscopic subjects in illustration of the use of hydroquinone as a developer.

Mr. A. MASEKILL then read a short paper on the same subject, giving the view taken of this reagent in France, and alluding to the advantage accruing from its use in developing bromide paper.

The discussion was continued by Messrs. Rodgers, Elder, Deed, Wilson, Noble, Orton, Graham, Balfour, Stormey, Betjemann, Grimshaw, King, Clark, Davison, and the Chairman.

On Thursday, January 17, Mr. Pringle will discourse on *Photo-micrography*. Apparatus and illustrations will be on exhibition. Meeting at eight p.m.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, January 3, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. L. Henderson presided, and, as the founder of the Association, he was warmly welcomed and congratulated on his comparative recovery from his recent illness.

Mr. J. B. R. WELLINGTON exhibited some excellent platinotype prints, and stated that one of them was faulty because he had neglected to stir the developer.

Mr. A. HADDON said: It is hard to see one's cherished idols demolished, broken, and trampled under foot, but if by so doing better substitutes can be erected in their stead it is a thing rather to be desired than to be regretted. There are many fallacies in photography, and at times, when they are supported by some of our leading men, it requires a considerable amount of courage to rise and endeavour to remove them and replace them by truths. In this very room, about a year or so ago, one of our authorities on lens matters told the meeting, when speaking of go-and-return shutters between the lenses of a doublet, that as soon as the smallest opening was produced by the moving part of the shutter that the light which passed through spread itself uniformly over the whole of the plate. At the time, though I said nothing, like the old woman's parrot, I thought a lot, and the result of my cogitations was that our authority was not quite correct in his dictum. I have always intended to appeal to Dame Nature in this matter, and I think her answer will be more to the point than the most powerful language I can command or the most elaborate diagrams I could produce on the subject. I have asked her ladyship a simple question, i.e., by cutting away a small portion of a piece of vulcanised fibre and placing it in the diaphragm slot. Her answer I now hand to the Chairman. I think it will be clear to him at a glance that when only a small eccentric opening is made that the light does not fall on the whole of the plate but is confined to a small portion of the field only. So much for small eccentric apertures between the lenses. Many present will perhaps remember that at our very last meeting, when discussing a certain question in connection with roller-blind shutters, it was stated that as soon as the slot in the blind uncovered the smallest portion of the lens the light admitted spread over the whole field uniformly. I endeavoured to illustrate on the blackboard that such could not be; but it was of no avail, the meeting was against me, and, according to the majority, the light still spread itself as they had said. We had no means at hand of proving the matter one way or the other, and I determined the very next time I had a few minutes to spare to try the experiment. Christmas is a merry time with most, in fact a lary time; with me it has been a period for experimenting, and one of the results I now lay before you. A small disc of opaque material with a segment cut off was placed as close to the front lens of a doublet as possible, and the result, as the negative shows, is that a portion of the picture is entirely absent. I again say, and I say most emphatically, that unless a considerable portion of the lens is uncovered the light which passes through is confined to a portion of the plate only. I remember, to my cost, the result of not carefully securing the focusing cloth on the front of the camera when exposing some plates instantaneously in Paris three years ago. In consequence of the wind the focusing cloth was blown down so as to partly cover the lens, a portion, and a portion only, of the plate received an impression, due to the light reflected from the Opera House, the rest was blank. If it is of no consequence whether the whole of the lens is uncovered or not, how is it that we are all so careful in pulling back the focusing cloth before exposing the plate by removing the cap? It cannot be simply because we cannot get the cap off that we attend to this small matter. The reason why all shutters in front of a doublet lens which opens at the centre and close up centrally give weak margins is because the edges of the lens are protected during a portion of the exposure, and no light can, consequently, fall on the margins of the plate. Shutters which open centrally and close again at the centre should be placed between the lenses, as in the case of Sands & Hunter's shutter, Wollaston's, and others of that class. The best places for shutters, therefore, according to these results, would be either between the lenses, so as to open and close centrally, or just in front of the plate. If by these few remarks I shall have convinced some that for uniform illumination a shutter cannot be placed anywhere, and that a stop, in order to be most effective, must be central, my time will not have been wasted.

Mr. HADDON then exhibited prints showing that the shutters he had described cut off a part of the image. He added that shutters should be placed between the lenses and should open at the centre.

A question in the box asked the percentage of relative difference in illumina-

tion given by a roller shutter in front of the lens and a roller shutter next the plate.

Mr. A. COWAN said that he believed that placing the shutter next the plate would give at least double the illumination. When the exposures were not to be excessively short more means of exposing the plate were available without such serious loss of light.

Mr. KERR thought that shutters in front of the lens gave more light than Mr. Cowan supposed.

Mr. WILLIAM ENGLAND, when taking instantaneous views of Paris in the old wet plate days, could only get sufficient light by a drop shutter next the plate; it fell from a bag above the back of the camera into a bag below. He believed that there was nothing to beat the roller-blind shutter next the plate. In reply to a request made by the Chairman, he added that he should be happy to show transparencies from those old instantaneous wet plate negatives at the next lantern meeting of the Association.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

An ordinary meeting was held on January 1 at Myddelton Hall, Islington, — Mr. E. Clifton, Vice President, in the chair.

Mr. W. T. COVENTON showed some bromide prints and a mounted silver print covered with small spots which were thought to have been caused by bronze powder.

Mr. L. MEDLAND asked if any chemical could be added to the developer which would give a warm tone to lantern transparencies without a previous long exposure.

Mr. CLIFTON thought that warm tones could be obtained only by giving a long exposure and using a suitable developer.

Mr. R. R. FULLER asked how to remove a black margin round an opal caused by the rabbit mark on the negative.

Mr. CLIFTON said that if the film were cut round with a sharp knife and the opal soaked in water the margin could be peeled off; this would not be noticed in the case of a vignette.

The ferricyanide reducer and rubbing down with pumice stone were also recommended.

Mr. MEDLAND asked how he could obtain a good transparency from a cracked negative without showing the crack.

Mr. CLIFTON said that if two thicknesses of tissue paper were put over the printing frame and the latter turned about in the hand before a gaslight turned down low no trace of the crack should be seen.

The HOS. SECRETARY said that the film could be stripped off the glass by means of hydrofluoric acid and a gelatine skin.

Tuesday, January 15, will be the annual dinner; Tuesday, February 5, lantern evening; and Tuesday, February 19, an exhibition of members' work.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

THE first annual exhibition and *soiree* of this Society was held at the West Norwood Institute on Thursday evening, January 3. Over two hundred and fifty prints were sent in for exhibition.

The Society offered three medals for competition, and Messrs. Gale and Davison acted as judges. They awarded the first silver medal to Mr. B. Wilkinson, jun., for a set of six platinum prints, and the second silver medal to Mr. J. Morris for a set of six in silver, and the third bronze medal to Mr. L. Wolff for a set comprising both silver, platinum, and bromide prints. Among those not sent for competition was a collection of thirty half-plate silver prints of views in the North of Scotland, the work of Mr. A. H. Leaf.

Among the main features of the evening were two lantern slide exhibitions. The first included some slides by Mr. A. R. Dresser, among which a series illustrating the various phases of a dog jumping into the water for a stick were very clever. Slides by Messrs. W. H. Baldwin, H. Senier, J. Downes, R. Crothwaite, F. J. Bright, and the Eastman Company followed.

The second exhibition included the works of a few masters in the art of lantern slide making, and was a combination of such excellence as is seldom seen together. The first series were instantaneous views in London, Brighton, and some continental cities, by Mr. F. Fincham, produced by the collodion process. Then followed a fine set by Mr. B. Wilkinson, jun., which included many of that gentleman's best-known pictures. Next came a contribution by Mr. L. Wolff, concluding with a splendid collection by Mr. J. Gale. The audience, which had frequently given evidence of its appreciation of the work of the various exhibitors, applauded again and again as Mr. Gale's slides were thrown upon the screen.

Over a hundred members and their friends attended the exhibition, and it is satisfactory to note that the sale of tickets very nearly covered the expense of the undertaking. The exhibition was held within two days of the second anniversary of the foundation of the Society, and the members are to be congratulated upon the progress made during that time.

The next meeting will be held at the West Norwood Constitutional Club on Tuesday, January 15, when a demonstration of lantern slide making will be given by Messrs. Senier and Wolff.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

On Friday night, January 4, at the ordinary fortnightly meeting of the above Society, held at the Institute, Beley, Mr. Pringle presided.

Mr. B. SHOTON exhibited a plate which had been given to him to develop; it had received a drop-shutter exposure in a room late on a summer evening, the subject being a portrait. Upon development he obtained, instead of a negative, a positive of a rich red colour.

In the discussion which followed it was stated that the red colour was red fog, and that if a plate received so extremely short an exposure a positive would be the usual result.

The President then introduced Mr. DRESSER, who gave the members an address upon *Hand Cameras*, illustrating his remarks by showing his camera,

and prints, enlargements, and lantern slides made from negatives taken with his camera.

The next meeting will be held on Friday, January 11 (this evening), on which occasion Mr. Hushon will read a paper entitled *Six Months in Switzerland*.

CRYSTON MICROSCOPICAL AND NATURAL HISTORY CLUB.

There was a good attendance of members at the ordinary monthly meeting of the Photographic Section of the above Club, held at the Public Hall, Croydon, on January 4.—Mr. W. Low Sarjeant in the chair.

Nearly two hundred lantern slides, the work of members, were thrown on the screen, and a selection made for exhibition at the annual general meeting of the Club on January 9. The new Club lantern was used for the first time and gave general satisfaction.

It was decided that, in addition to the ordinary monthly meeting, a special monthly lantern slide exhibition should be held on the third Friday in each month during the winter season.

On February 1, Mr. Bellsmith of the Eastman Company will give a demonstration of *Transfertype and Printing and Enlarging on Bromide Paper*.

SHEFFIELD CAMERA CLUB.

The first annual general meeting of the Club was held on Friday evening, the 6th instant, at the rooms of the Society, 8, Fitzalan-square. The chair was occupied by Mr. Morton.

The minutes of the previous meeting having been read and confirmed, Mr. W. Jenkinson was duly elected a member of the Club.

The officers for the ensuing year were then elected:—*President*: Dr. Thomas H. Morton. — *Vice-Presidents*: Messrs. B. W. Winder, F.C.S., and G. E. Moleham. — *Committee*: Messrs. C. F. Coombe, M.R.C.S., J. O. Arnold, F.C.S., E. Howarth, F.R.A.S., G. T. W. Newsholme, M.P.S., J. H. Rawson, and C. Yeomans. — *Treasurer*: Mr. W. Gilley, jun. — *Hon. Secretary*: Mr. Henry J. Hanly, F.C.S.

The condition of the Club, both financially and otherwise, is most satisfactory, and larger and more commodious premises, which will include a lecture hall, reading room, and dark room, are shortly about to be taken.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

The usual monthly meeting of this Society was held on January 2.—Mr. Concorlier Andrews in the chair.

Mr. F. W. Dix read a paper on *The Carbonate of Soda Developer*, pointing out its merits and disadvantages. The paper was illustrated by some negatives and transparencies produced by the developer, which were much admired; and several members expressed their intention of giving the developer a trial.

After the question box had been opened and the queries replied to, the chair was vacated and the discussion took a conversational turn and was continued for some time.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

The usual fortnightly meeting of the above Association was held on the 7th instant.—The President, Mr. Henry Blandy, L.D.S. Edin., in the chair.

Mr. J. Henry Hanly, of Oak Lodge, Kimberley, was elected a member.

The President in his opening remarks referred to the monthly circular issued for the first time this month, and congratulated the Committee on the new departure they had taken in this matter, as he had no doubt it would be very beneficial to the Society's prosperity. He was also pleased to see that they were taking steps for the formation of a reference library on photographic subjects. He then introduced:

Mr. H. S. BELLSMITH, of the Eastman Dry Plate and Film Company, who explained and demonstrated before them the processes for which this Company is famous. Mr. Bellsmith also explained the working of the Kodak camera. A quantity of film negatives were then handed round for inspection, and also flexible enlargements taken by the Kodak camera and larger negatives.

Many questions were asked by the members, which were fully answered by the lecturer.

Mr. BOLAN proposed a vote of thanks to Mr. Bellsmith, who in acknowledgment said that he had visited many photographic societies since his arrival in England, but he had not been in such comfortable rooms with but one exception.

The meeting was largely attended.

OLDHAM PHOTOGRAPHIC SOCIETY.

On Thursday evening last the annual supper in connexion with the above Society was held in the Freemasons' Hall, Union-street, between thirty and forty members and friends being present. The evening was spent in an agreeable manner; vocal and instrumental music, recitations, &c., were given by members and friends. Representatives of London and provincial societies were present.

This being the Society's twenty-first anniversary, the Hon. Secretary and Librarian recognised the event by presenting to each member a suitable card of a unique character, the description of which is as follows:—The background is formed of the covers of twelve of the principal photographic journals and almanacs. In the centre is a photograph in miniature of members of the present Council, below which is the coat of arms of the borough of Oldham and the Society's presentation print for the year 1888; in the top left-hand corner is a photograph of the first meeting-place of the Society; on the same side, at the bottom, is a list of the first Council formed in 1867; in the top right-hand corner is a photograph of the Lyceum, the present meeting-place; in the corresponding corner below is a list of the present Council for the year 1888; the whole is surmounted by a photograph of the President (Mr. Greaves).

The toast, "Success to the Oldham Photographic Society," coupled with the

name of the President, was proposed by Mr. J. CHADWICK and suitably acknowledged.

A pleasant evening was spent, the party reluctantly breaking up about twelve o'clock.

Correspondence.

Correspondents should never write on both sides of the paper.

PHOTOGRAPHERS' DEFENCE UNION: POLLARD VERSUS PHOTOGRAPHIC COMPANY.

To the Editor.

SIR,—I suggested in the columns of a contemporary, some weeks ago, the formation of a Photographers' Defence Union, but did not anticipate the idea would be adopted for the furtherance of a cause such as Mr. Hubert advocates.

It would be a disastrous start for such an undertaking to take up such a case as is proposed. If, as Mr. Hubert remarks, there is no direct case as to photographs, the case of Tuck *versus* Priester, cited by the judge in Pollard *versus* Photographic Company, is so strongly in point that an appeal against his judgment would, I fear, be hopeless. In that case, decided in 1887, the plaintiffs employed the defendant, a printer, to make them copies of a drawing of which they had the copyright. He executed the order, and without their knowledge or consent made other copies and sold them in England. It was held by all the Judges of Appeal that there was an implied contract not to make any copies of the drawing other than those ordered by the plaintiffs, and that, independently of the Copyright Act (which, however, was of some use to them), the plaintiffs were entitled to an injunction and damages.

Mr. Hubert says photographers have always thought they possessed the copyright, and not the sitter. I do not think many will agree with him. A reference to the Copyright Act, 1862, will at all events dispel the illusion. Not the less is a Photographers' Defence Union a desirable thing if properly taken in hand.—I am, yours, &c., S. J. DEBENHAM.

January 7, 1889.

To the Editor.

SIR,—Though I must acknowledge your wisdom in curtailing a paragraph of my letter in last week's issue, I must say that it cannot fail to weaken my argument considerably, and when, in addition to this, "Junius," in *Echoes*, pronounces the proposed society powerless on account of the uncertainty of the law, my scheme would almost seem doomed to failure but for the fact (which will be apparent to most) that "Junius's" argument is as poor a one as could possibly be advanced, for the principal aim of such a society should be to convert such an uncertain law into a definite one, and furthermore to guard against possible chances of one judge's common-sense view running in an opposing direction to that of another, or, what is more, to that of the whole photographic profession. Moreover, the very name of a trade protection society would cause intending litigants to reconsider any hasty or haphazard step, it being well known that these bodies carry cases to the highest courts. The very gist of "Junius's" argument is against him, because the pictured happy-go-lucky way of magistrates, &c., is the strongest reason that that tendency should be checked.

A society as proposed would, of course, be represented by the ablest counsel, and supported in its defensive proceedings by scientists of the first order.

It must also not be forgotten that the case Pollard *versus* Photographic Company is not the only type that may crop up. There are such where the surveyor interferes with the skylights, customers suing photographers for the return of money on the ground that in *their opinion* the picture is unlike, &c.

I propose shortly to call upon the leading photographers with a view of enlisting their sympathies and to hear their opinions.—I am, yours, &c., Royal Photographic Studio, 238, Mare-street, Hackney. J. HUBERT.

P.S.—I suggest 5s. for the annual subscription, and the solicitation of outside help in exceptional cases.

[We curtailed the paragraph referred to as it offered a chance for an action for libel.—ED.]

To the Editor.

SIR,—It appears to me that photographers would be exceedingly ill-advised to accede to the request made by Mr. J. Hubert in your last issue, that they should subscribe for the expense of an appeal in the recently decided case of Pollard *versus* The Photographic Company. Had such a course been proposed in the case of Marston and Barnes, in which a County Court judge decreed that the negatives taken by the photographer had to be given up to the customer ordering the photographs, a proceeding at variance with the practice and understanding well settled in the profession—at variance also, I believe, with decisions that have been pronounced by other courts—there would have been much to say in its favour. In the present instance, however, the contention on behalf of the defendant was that a photographer is at liberty, without the consent of the sitter, to make what use he pleased of a portrait negative of a lady

customer. The case was fully gone into by an able judge, who, after postponing judgment for further consideration, decided that the photographer has no such right. I suppose that photographers, for the most part, will willingly admit that they do not desire to assert such a claim as that put forward; indeed, Mr. Hubert himself, in another part of his letter, says, "No respectable photographer would part with any copies other than to the sitter or relatives, or with the former's permission." Rather a severe comment upon the proceedings of his friend, for whose cause he now asks subscriptions. "Thrice armed is he who has his quarrel just." If photographers do band together to have some test case reheard, let it be one which vindicates a principle of which they can approve.

The customary proceeding and understanding amongst photographers with regard to possession and use of the negatives of private sitters is one which has the sanction of many years, and will, I believe, be found to be in accordance with common sense, and for the most part with such judicial decisions as have been given in the courts of law. It may be briefly stated as follows, of course supposing that no special arrangement has been made:—

The negative is the property of the photographer, who has, however, no such copyright in the work as to prevent the sitter from having any kind of copy made from the prints with which he may have been supplied.

The use of the negative is joint. The sitter cannot, of course, print from it without the photographer's consent, and the photographer has no right to do so without the sitter's consent.

The case put by Mr. Hubert, that it will be necessary to obtain the consent of each individual in a group before supplying copies, is, I think, a little fanciful. The photographer, in the absence of notice to the contrary, would probably be held justified in supplying copies to any member of the group; at all events, the person who originally ordered and paid for the copies would be presumed to be entitled to order further copies.

The case of portraits printed as specimens merely is a little different. There are many, probably most people, who do not object to such use being made of their portraits, but who yet would not give any written consent to it. They would fancy that the doing so would make them appear vain of their personal appearance. Moreover, whilst they have given no consent, they are at liberty, at any time, to request the removal of the specimen. Here, again, custom has established a common-sense proceeding, at all events amongst the right-feeling. If any objection is made to the use of a portrait as a specimen, such objection is at once met by the withdrawal of the picture.

If it could be supposed, which appears to me exceedingly improbable, that the ruling of Mr. Justice North can be disturbed, and the contention of the defendant that a photographer is at liberty to make what use he pleases of his customer's portrait were to be established, there would, in all probability, arise such an outcry from the public, that legislation injuriously affecting the photographer's rights might be speedily looked for. In this view, the success of an appeal in the case of Pollard *versus* The Photographic Company would be the worst misfortune that could happen to photographers.—I am, yours, &c., W. E. DENHAM.

OWNERSHIP OF THE NEGATIVE.

To the Editor.

SIR,—The letters on the copyright and the ownership of negatives of portraits taken in the usual course of business, and for which we have been paid, which have appeared from time to time in your excellent JOURNAL, seem to me very much away from what the profession ought to discuss for their own interests.

The law is very definite that the copyright of such portraits is not ours. Then why store the negative? *As honest men we cannot use it for ourselves*—that is, for our own interest—in any way whatever without permission. Then why keep it? Why not settle the vexed question at once by cleaning what some incorrectly call their loss of trade, but what I call the portrait itself? Wipe the portrait off. Doing so would benefit the profession. More portraits, more sittings. And if one particular portrait was wanted—copy it. The copyright and ownership of the negative would then be easily and satisfactorily settled. "Lead us not into temptation" ought to be the prayer of many photographers; for the fact cannot be denied that many abuse the confidence placed in them.

The decision in the case "Pollard *versus* the Photographic Company" is a wise and a just one. And I consider that to ask the profession to defend and justify a wrong is an insult.

The letter dated from the Camera Club is scarcely a wise one, and gives evidence that the writer has not read the correspondence which has appeared on the question. The law is well defined and explained by Le Nève Forester in an article in the JOURNAL ALMANAC for 1869.

The law relating to photographs will be altered I have not the least doubt; and it behoves us, as practical men, to look at the probable alterations in a business manner. Perhaps some of our business men will suggest what alterations should be made that would make the law fair and honest alike to the public and the photographer.—I am, yours, &c., J. T.

January 5, 1889.

INTENSIFICATION.

To the Editor.

SIR,—Referring to an article under this heading, printed in No. 1495, your contributor, "Junius," asks, *inter alia*, "Why mercuric chloride?" Read by the light of the sentence immediately preceding the interrogative, I imagine that it was intended to run, "Why mercuric bi-chloride?" I hasten to say that my use of this latter term was due to a slip of the pen. If "Junius" will do me the honour to cast another glance over the article, he will find Hg Cl₂ correctly named in two or three places. It is unfortunate that your contributor, in attempting to put me right, should himself have stumbled.

I have no desire to be understood as fathering the proposition that the Ag Cl of the double salt sensibly darkens in the light—although, from observations made a year or two since, I was temporarily led to believe that an appreciable alteration does sometimes take place. My reason for recommending the avoidance of direct sunlight during intensification arises from the fact that I am not wholly disinclined to favour the hypothesis that, under some conditions, the solar rays induce a latent action in the Ag Cl, and that possibly to this cause may be traced, in a partial degree, the fading to which the mercurially treated image of a gelatine negative is often susceptible.

I grant that the particular passage dealing therewith lacks the perspicacity that might, upon reconsideration, have been imparted to it; but I am unable to agree that the suggested method of adding K Cl to the mercury solution is "needlessly roundabout." The operation is the work of a few seconds. The stated solubility of many substances at, say, sixty degrees—an unknown natural temperature for several months of our year—is often delusive. I recommend "Junius" to try the experiment of making the addition both ways, to note the time occupied in dissolution, and to compare the appearances of the resulting compounds. The point, however, is of slight moment.

It is interesting news to me that the practice of adding K Cl to the mercury solution is of "frequent" occurrence. I do not hesitate to avow that until I mentioned the plan myself I believed that it had not been described. As I gather that "Junius" has an acquaintance with the works of the accepted authorities upon photography and chemistry, he will, perhaps, be good enough to refer me to a published formula in which potassium chloride figures as a constituent of the mercury intensifying solution. The mighty mass of photographic literature deters me from passing upon him the harsh sentence of wading through any but the smallest fraction of it. I will, therefore, only indicate at random two standard books in both—or one—of which it should surely find a place. These are, Abney's *Instructions* (1884 edition), and THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, 1889.—I am, yours, &c., THOMAS BEDDING.

THE ETHONOL LIGHT.

To the Editor.

SIR,—I learn from a communication to your JOURNAL, of December 14, p. 789, that Mr. Hardwich is using the old style of Ives' ether saturator. It will interest Mr. Hardwich, and others, to know that my improved single tube saturator is the only form now made in this country, and that the petroleum ether, recommended by me, is also now generally used here in preference to sulphuric ether. A paper describing these improvements was reprinted in your JOURNAL some months ago.—I am, yours, &c., FRED. E. IVES.

2750, Eleventh-street, Philadelphia, December 26, 1888.

COPYING OIL PAINTINGS.

To the Editor.

SIR,—"Pictor," in his last communication, states a truism, "that common sense is not technical knowledge," but technical knowledge is in a great measure compounded of common sense, and, so far as its application to this discussion is concerned, it is very certain that, without common sense, technical knowledge would be of little avail, but this he inferentially ignores. So much for his argument.

Again, glycerine seems to be a particularly objectionable substance to "Pictor," because it will not dry alone. Glycerine and water is the mixture advocated, and this will dry, slowly or not, according to the proportion of glycerine. Are not moist water colours compounded with glycerine? Yet water colours dry. In its application to oil paintings just so much glycerine is added to the water that the otherwise rapid evaporation of the water is retarded. If the painting is to be several days under treatment, as inferred by "Pictor," common sense would indicate drying off after each day's work. Moreover, moistening the surface to bring out detail can scarcely be called saturating the substance.

If "Pictor" objects to any preparation of an oil painting before copying, he will not, I fancy, have many with him if the best possible results are expected; but "the wilful" men maun hae his way."—I am, yours, &c., E. DUNMORE.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.—The Annual General Meeting of the Club will be held in the Iron Room, Granville-road, Stroud Green, on Monday evening next, the 14th instant, at eight o'clock. Business.—The election of officers for the year 1889, and to confirm (if approved) the report of the past half year.

Exchange Column.

* No charge is made for inserting Exchanges of Apparatus in this column ; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange a C. D. V. lens, by Jamin, for a good half-plate rectilinear ditto.—Address, C. BASSON, 364, Harrow-road, Faldington, W.

Desire to exchange Kodak and lantern slides of Irish views given in exchange for quarter or half-size dry plates.—Address, EDWARD J. HUGHES, Graigne, co. Kerry, Ireland.

Wanted, Kodak or other detective camera, also half-plate set, in exchange for first-class backgrounds and accessories and Benth's four and a half inch mitring machine.—Address, W. S. ANDERSON, Ilkerton.

Answers to Correspondents.

* Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co., 2, York-street, Covent Garden, London, W.C."

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPHS RESHARED:—

Mr. A. SUMMONS, London.—Three photographs taken by the flash light.

F. H. HANDY (N. Z.).—Received. Thanks.

RECEIVER.—D. Johnson and Harding Warner.

M. J. E.—The process is not protected by patent.

STEELE & STEWART (Edinburgh).—The Platinotype Company, 29, Southampton-row, London, supply the paper.

YELLOW STRAIN.—Try the effect of a dilute solution of cyanide of potassium. We fear, however, the case is hopeless.

ARTIST inquires if America, or Australia, or any of the Colonies, is a good field for a photographer and portrait painter, and which is considered the best.

J. T.—Any good cemented doublet of the "rapid" class, and having a focus of from ten to twelve inches, will answer your purpose. A single lens would be rather too slow.

C. WILSON.—If you make the work copyright you must register it at Stationers' Hall. This should be done before any copies are issued, otherwise there will be no copyright in them.

H. T. SHEPARD, M.D.—The silver is converted into the ammonio-nitrate by first dissolving the nitrate in distilled water and then adding ammonia, drop by drop, until the precipitate, which at first is thrown down, is all redissolved.

THOMAS J. O'CONNOR.—Seven reliable formulae for a hydroquinone developer are given on pages 631-3 of the current ALMANAC. Let our correspondent commence with No. 1, and adopt that which best suits his special requirements.

LEADS.—1. The lens you mention will make a negative sufficiently large to fold all that is required.—2 and 3. Having taken the negative, say a cabinet size, send it to any of those who advertise as printing for the profession and they will do all the rest.

H. K. W.—We know of no places. Study the portraits taken by good artists and begin by imitating them closely both in lighting and pose. In this way you will soon immensely improve yourself in art knowledge. Also read any good works on composition.

H. WORLEY inquires where he can obtain the proper optical glass to make a photographic lens.—Messrs. Chance Brothers, Birmingham, supply optical glass; it may also be obtained from Houghton & Sons, Holborn, or from Birtley & Co., Soho-square.

R. T. J.—1. See the collector to the County Court.—2. If by opalines you mean prints in optical contact with glass, they must be in contact all over and not at margins alone.—3. Dry all the silver residues, mix them together, and keep the gold residues apart.

G. H. A.—Your trouble arises from the presence of iron. After the precipitate from old toning baths, thrown down by sulphate of iron, is collected, it should be treated with either sulphuric or hydrochloric acid to remove all traces of iron; then, after well washing, it is ready for dissolving in the aqua regia.

T. writes: "I have got a pen-and-ink testimonial to photograph—it is written in violet ink—and no matter what light I take it in the result is as faint as to be useless. Can you suggest a way out of my difficulty?"—The secret of success lies in the adoption of orthochromatic or isochromatic plates.

R. A. (Cambridge). To copy a cabinet picture the same size with a lens of nine inches focus the camera must be capable of extending to eighteen inches. By the way you write we suspect you have taken the back focus of the lens and not the equivalent focus. If this be the case the camera will have to be a few inches longer still.

F. DUNSTONVILLE.—In the toning of the transparencies, the washing after the mercurial treatment was not sufficient, hence the lights become stained with the sulphide of potassium. If you refer to the article in the JOURNAL for November 16 you will see particular stress is laid upon the absolute necessity of perfect washing between each operation. We fear there is no way of removing the stain now. You might, however, try the effect of a brief immersion in the solution of bichloride of mercury.

S. A. R.—The sample of glass sent would be quite safe if only a feeble light, such as a night-light, were used; but with a stronger source of illumination or with daylight it would be dangerous.

A. RICHES wishes to know how to give a ground-glass appearance to a large window at which he intends to attempt portraiture. He has been recommended to stipple the glass over with white paint, but he does not want to do that as it will be only a temporary arrangement, and the paint would be difficult to remove.—Make up some starch paste (rather thin) and then mix some common whitening with it. This stippled on the glass answers very well. Tissue paper attached to the glass with paste is an excellent way of subduing the light, and it is easily removed.

R. C. MACLEOD inquires: "1. What is the safest and most powerful form of limelight for the magic lantern?—2. Can one now with any form of limelight be absolutely secure from risk of explosion? if so, with what form?—3. I have the lantern lens four-wick lamp, &c., with the light of which I am dissatisfied; at what cost could I get limelight fittings?"—In reply: 1 and 2. The most powerful light is that obtained by a mixed gas jet; the safest jet is the blow-through.—3. Limelight burners cost from twelve to twenty-five shillings. One of fairly good quality will cost halfway between these sums. But a bag or bottle for compressed gas will also be required. Better get an estimate from some of those specialists who advertise in the ALMANAC.

A. GLASS writes: "Wanting to cement the front combination of a large portrait lens, I got some Canada balsam from the local chemist, which proves to be too thick, as I cannot force it to the edges. Will you kindly say if it can be thinned, and what with, also method of cementing? Also is there any advantage in its being cemented as against leaving it undone?"—In reply: The balsam may be thinned by the addition of turpentine. To cement the lenses, have the contact surfaces made quite clean, using ether or benzole to remove all traces of the former cement. Place a drop of the balsam on the centre of the concave surface, then apply the other lens with a gentle pressure, so as to cause the balsam to ooze out all around the edges. The advantage of cementing is that two reflecting surfaces are nullified.

SCOTTS writes as follows: "A class of view which is especially common at this time of the year is where there are large masses of shadow and also of bright sunlight, the former perhaps being in the near foreground. Street views are an instance. How ought these to be treated? 1. Should exposure be full, or bare, or just right?—2. Should the negative be made thin or dense?—3. Should the extreme shadow be clear (or at least nearly clear) glass, or should it have a fairly deep deposit? (Of course, I do not refer in this question to fog.)—4. Would a slight fog on plate help?—5. Whether is tentative or quick development more advisable? I know that such a view should be taken when there are white clouds, but my queries are intended to deal solely with exposure and development.—6. Would you kindly inform me if any type of transparency to expose by contact would answer the same purpose?"—In reply: 1. The exposure should be full—sufficient to secure detail in the deepest shadows.—2. Not too dense.—3. Only the extreme shadows should be clear glass.—4. Not if the negative be good.—5. A tentative development, so as to obtain all the detail in the shadows before the lights acquire too much density.—6. This query is not clear.

THE CHAMPION PHOTOGRAPHIC EXHIBITION.—This exhibition of works which have taken prizes at other exhibitions is now open at the Fine Art Society's Rooms, 148, New Bond-street, London. There are one hundred and ninety-three frames, and these comprise many of the finest photographs that have been displayed at other exhibitions. We shall give a more detailed account of it on an early occasion, and meantime recommend our readers to pay it a visit.

CAMERA CLUB.—The second of the "one man" series of photographic exhibitions is now open at the Camera Club. It is composed of large direct pictures in platinum by Mr. Harry Tolley, of Nottingham. This gentleman has made for himself so good a reputation as an artist that all ought to avail themselves of this opportunity of seeing his works under such favourable auspices. The exhibition was inaugurated by a smoking concert on Monday evening.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of the Club, January 16, 1889, will be on *Hydroquinone*.

HUDERSFIELD PHOTOGRAPHIC SOCIETY.—January 16, at eight p.m., demonstration by Mr. H. J. Bellsmith, of the Eastman Dry Plate and Film Company.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—On Thursday, January 17, Mr. Friese Greene will read a paper on *Photography by Means of the Eye*, also *The Effects of a Bromide Plate under Pressure and in a Vacuum*.

HASTINGS AND ST. LEONARDS PHOTOGRAPHIC SOCIETY.—Next meeting at the Brassey Institute, January 14. Exhibition by limelight of lantern slides contributed by members. All members are invited to leave their slides with the Hon. Secretaries before the date of the meeting.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1498. Vol. XXXVI.—JANUARY 18, 1889.

THE REACTIONS OF MERCURIAL SALTS ON INTENSIFYING SOLUTIONS.

MERCURIAL intensification has, rightly or wrongly, gained anything but a favourable reputation in connexion with gelatine negatives, owing to the alleged want of permanency of its results; though, on the other hand, there are very many who deny that this character is deserved, or at least that the fault belongs entirely to the method. Very probably the supporters of the latter view are correct, for it is not at all unlikely that, considering the complex reactions that occur between the soluble salts of mercury and other metals and alkalis, mismanagement on the part of the operator is too often the cause of the trouble. It may not be amiss at the present time to briefly summarise the chief reactions that occur in the commonly used intensifying solution of mercuric chloride, especially as a controversy on the subject is now proceeding between two of our contributors.

Mercuric chloride or, as it was formerly called, bichloride of mercury has been applied to photographic purposes from the very earliest days, both as an intensifying agent and also in the production of the once popular and, when well executed, really beautiful "alabastrine" pictures, consisting of a collodion positive on glass bleached to a pearly whiteness by means of a solution of the mercurial salt. This bleaching action—which is not confined to the mercuric chloride, but is shared by the chlorides of other of the dyad metals whose affinity for chlorine is less than that of silver, notably cupric and ferric chlorides—arises from the decomposition of the mercuric chloride by the metallic silver forming the image. In the interchange that takes place, one of the atoms of chlorine of the HgCl_2 becomes dissociated from the latter and goes to the silver image forming AgCl , mercurous chloride or calomel being formed at the same time. The latter salt being insoluble is necessarily precipitated, and either remains in the liquid or is deposited in and upon the film under treatment, probably also taking an important part in the formation of the new image.

The first question that naturally arises in connexion with an image composed chiefly of silver chloride, and containing traces also of mercurous chloride, is its liability to change when exposed to light. Chloride of silver we know in the pure and moist state rapidly darkens and is decomposed when submitted to light, though when perfectly dry it undergoes little, if any, change under similar circumstances. Mercurous chloride, too, the text-books tell us, darkens and becomes grey under the action of light, so that we might fairly predict for the bleached

image but a brief life. In the face of this, however, we have the fact that the alabastrine pictures of a former generation are still in existence in apparently their original state, and failing any record of experiments proving the contrary we may assume such images to be as reasonably permanent as any other in which silver forms a part.

The sensitiveness of chloride of silver to light is destroyed and its darkening prevented by many substances, as is well known, such as nitric acid, chromic acid and the chromates, chlorine, and such of the chlorides as we have mentioned above; but whether the immunity from change possessed by the bleached image depends upon the action of minute traces of mercuric chloride left in contact with it in the film, or whether its permanency is inherently due to its composition, there is no direct evidence to prove. It is most probable, however, that the latter is the case, for we may consider that, as the action of light upon silver chloride sets free chlorine, which in turn would combine with any mercurous chloride contained in the image, converting it to the mercuric state, there is always present as the result of exposure that which will prevent the darkening of the deposit, for it must be borne in mind that the dissociation of the elements commences before any visible colouration of the silver salt takes place.

Another important point, especially when a plain solution of mercuric chloride is employed, is the formation of the mercurous salt. In the old collodion days no trouble arose on this score because of the nature of the material forming the film, but with gelatine the case is altogether different. The absorbent character of the latter, and the powerful manner in which it clings to any insoluble matter that may be formed on it, are well known, and consequently it is of the greatest importance to prevent, as far as possible, any formation in the gelatine film of the insoluble and objectionable mercurous salt. Objectionable in more ways than one, for, while even in its unaltered condition it will deprive the shadows of their transparency and so destroy contact and increase the time occupied in printing, it will produce still worse results when darkened by the application of the final solution used in intensification. Fortunately, a large proportion of the calomel so formed remains suspended in the solution itself, as any one may notice from the turbidity that occurs in use with a plain solution of bichloride; still, a portion of the solution is absorbed into the film before decomposition commences, and the insoluble salt precipitated from this remains *in situ*.

This precipitation is prevented by the addition of a variety of substances to the mercuric chloride solution, *inter alia*,

by hydrochloric acid, or any of the alkaline chlorides, which may therefore be used with advantage in combination with the mercurial salt. As a matter of fact the latter are, and have been from the earliest times, so used, though principally for a different purpose, while hydrochloric acid has been specially recommended for the purpose of preventing the formation of this deposit, either in film or solution. The proverb says that "prevention is better than cure," and in this case it is emphatically so, owing to the tenacity with which gelatine clings to any deposit formed in its pores, otherwise the practice of soaking the film, after bleaching, in a solution of an alkaline chloride or weak hydrochloric acid would equally serve the same purpose.

Bichloride of mercury is a salt that is slowly and sparingly soluble in pure water, but its solubility is both increased and hastened by the addition of any of the alkaline chlorides with which it forms double salts possessing a greater degree of solubility than its own. Mercurous chloride, or calomel, which is practically insoluble in water alone, becomes soluble when the addition of a soluble chloride is made, or, more correctly, it is converted into mercuric chloride, which dissolves. Hydrochloric acid has a similar effect. Thus it will be seen that the addition of a soluble chloride to the mercury solution, originally made for the purpose of increasing the solubility of the bichloride, performs an additional and even more important function in preventing the deposition of insoluble mercurous chloride.

We next come to the action of alkalis upon mercurous and mercuric chloride, these being the agents generally employed as the after applications to produce density in the previously bleached image. This side of the question affects not only the colour and degree of density of the final image, but also the character and extent of the fog or veil produced in the case of carelessness in manipulation or insufficient washing. The behaviour of the fixed alkalis in this respect differs somewhat from that of ammonia, upon both the mercurous and mercuric salts. With calomel, aqueous solutions of the fixed alkalis produce a dense black discolouration, owing to the formation of mercurous oxide, but in the case of ammonia the black substance formed is a compound of chlorine, mercury, and ammonia, known as chloride of mercurous ammonium. The caustic alkalis may, therefore, all be employed as final applications, but the action of the carbonate is not sufficiently definite or uniform to recommend them.

Sulphuretted hydrogen and the alkaline sulphides convert calomel into black mercurous sulphide, which is insoluble in nitric acid and excess of sulphide of ammonium, but soluble in sulphide of potassium. Sulphide of ammonium may, therefore, be used for darkening the image, but the potassium salt, if used in excess, would tend to reduce it. There are many other substances that decompose mercurous chloride, and may be used for darkening the image, but they possess no features to recommend them over those already mentioned.

The aqueous fixed alkali instantly decomposes mercuric chloride with formation of mercuric oxide in the form of a dense orange-yellow precipitate and chloride of the alkaline metal. Aqueous ammonia and ammonium carbonate cause a white precipitate composed of oxide and carbonate respectively of mercurammonium. The carbonates of the fixed alkalis precipitate brown mercuric carbonate. If, however, a salt of ammonia accompany the mercuric chloride in solution, then the fixed alkalis, either in the caustic or carbonated condition, throw down first a white precipitate of the mercurammonium

salts, and, if added in excess, subsequently mercuric oxidized carbonate. Our contributor, Mr. Thomas Bedding, appears to have been speaking of a solution of chloride of mercury with chloride of ammonium as generally used, and not of a plain solution of bichloride, as his article would lead us to suppose. The sulphides form black mercuric sulphide.

With regard to the comparative effects produced in intensification by the different substances employed to darken the image, there is, perhaps, not a great deal of difference, except such as arises from varying degrees of concentration. The oxide of mercurous ammonium formed by the application of aqueous ammonia is, however, said to be unstable under the action of light—with what justice we are not prepared to say—but ammonia remains undoubtedly the favourite application.

The effects produced upon imperfectly washed films will, however, vary very materially from decomposition of the unremoved mercuric chloride. Thus, while ammonia would only throw down a white, or slightly yellow, precipitate of oxide, or carbonate of mercurammonium, producing a sickly yellow veil over the whole negative, the fixed alkalis, either caustic or carbonate, are bound to give a more or less pronounced brown or black colour, and the same may be said of the sulphides. Too many of our readers are familiar with this black veil, which appears sometimes unaccountably. Upon inquiry it will, perhaps, be found it has occurred when the final intensifying agent has been varied from ammonia to one or other of the substances last named.

These remarks may, we trust, serve to explain some hitherto existing discrepancies in many minds, and will, at any rate, direct attention afresh to the absolute necessity for thorough washing in every part of the process of mercury intensification.

"INSTANTANEOUS" EXPOSURES.

ONE frequently sees written on a photograph, or may be told, that it was taken in some extraordinary brief space of time—sometimes the fiftieth, the hundredth, or a still smaller fraction of a second—when even a casual examination, by one understanding the matter, will show that the exposure was of a much longer duration. In some instances a little consideration and calculation would prove, by the extent of the blurring of the image, that the time of exposure must have been, often, as much as ten times that stated. Now the producer of the picture has no intention of deceiving, as he fully imagines that the time stated was really the correct one, inasmuch as his shutter was said by its maker to work in the period mentioned. The manufacturer made the statement in perfect good faith, because the instrument, when it left his hands, was capable of giving fairly accurate exposures, according to the speeds marked on the index. But how long is this accuracy maintained after a shutter is taken into every-day use out of doors?

There are so many disturbing causes which may impair the accuracy in the working of the instrument. Springs, it is well known, will get weaker with use; and this, after a time, will cause a retardation in the speed of the shutter. Working parts will wear away; and this may make the shutter work faster or slower, according to circumstances. Sometimes the pivots or bearings are lubricated with oil; this may corrode, or accumulate dust and dirt, and so produce a slowing action. The shutter itself, or any of its bearings, may become imperceptibly bent; and the friction arising therefrom will produce a marked effect on the rapidity. The more intricate the

mechanism, the more liable is the speed of the shutter to be influenced by extraneous causes.

We recently saw a shutter which had been in use for some time, when the speeds marked on the index were of no value whatever. When it was set for the fifth of a second's exposure the time was fully half a second, and when set for half a second the exposure was quite a second and a half. This was due to one of the sliding metal plates having become very slightly bent; but so trifling was the injury that it had hitherto passed unnoticed. Even the simplest form of drop-shutter is liable to variation. For example, a particle or two of grit in the groove will usually have a decided influence in modifying its speed; and if the moving parts be of wood, a little moisture will, in addition, increase the effect.

Now instantaneous shutters are generally employed under such conditions that it is impossible to avoid their rate being subjected to various disturbing conditions. For instance, when working on the beach spray and moisture from the sea cannot be prevented from reaching the instrument, and if it be of metal it is liable, after a time, to become corroded, or if of wood to become swollen or warped. Again, when the apparatus is worked in a dusty road, or possibly carried on a bicycle, it is impossible to avoid gritty particles from gaining access to the working parts. Hence such an amount of friction may be introduced as will considerably impair its action. However, sufficient has been said to show that, so far as shutters which have been subjected to the ordinary vicissitudes of outdoor work, no actual reliance can be placed on them as regards the real measurement of the time of exposure, notwithstanding that they may have been accurately rated at the time of manufacture.

One point in connexion with shutters may be alluded to here, namely, that they seldom receive at the hands of their employers that care which is essential to retain them in their original working condition. Some of them are really delicate pieces of mechanism; yet they are usually subjected to much rougher usage in handling, working, and in packing, than are most instruments of a similar character. However, the actual measurement of the duration of the exposure, except for scientific purposes, is of little real moment, so long as the shutter secures the effect desired. This brings to our mind another topic.

Is absolute instantaneity, as the term is understood, desirable? For most scientific purposes, or as a photographic achievement, it decidedly is; but pictorially it frequently is not, simply because it may convey an impression precisely the reverse of that intended. Indeed we have seen many examples, where the exposure has been a near approach to instantaneity, that, instead of conveying the idea of life and action, the moving objects appeared to be in a state of absolute immobility.

This subject was well illustrated, many years ago, by the late Mr. Rejlander, who produced two pictures of a girl at a spinning wheel. One showed the effect of an instantaneous exposure, and the other, one of some seconds' duration. The former picture had the spokes of the wheel as well as the foot of the worker sharply defined. The effect was that the wheel and the girl were at perfect rest. The picture which received the longer exposure had, of course, the spokes of the wheel, together with the foot of its worker, very indistinct, but it showed motion and conveyed the best impression of an "instantaneous picture." Here is another illustration. If, say, a bicycle driven at a rapid speed be photographed instan-

aneously, the spokes of the wheels, as well as the feet of the rider, will be perfectly sharp, hence the machine and its rider will seem to be perfectly motionless, as if waiting to be photographed. Such a picture may be a triumph photographically, but it does not convey the idea of reality. The same may be said of a railway train, however fast it might be travelling, if the exposure were sufficiently rapid to secure the spokes of the wheels and the outlines of the engine and carriages perfectly sharp. Such a picture would represent the train as standing perfectly still, as if stopped by a signal, for there would be nothing in the picture to indicate that it was moving.

In the portion of Mr. F. C. Beach's article on *Collodio-Bromide Emulsions*, published in our last issue, we notice that he gives a formula for an albumen substratum. Now this form of preliminary coating is all very well where an acid developer is employed, as in the wet collodion process—though there it is said by many operators to throw the bath out of order—but when alkaline development is used it is scarcely of much value, since the alkali dissolves the albumen, and more thoroughly loosens the collodion film from the glass than if it were left to its own resources with a first grip of the glass surface. That the substratum fails in keeping the film on the plate is proved in this case by the recommendation to edge with indiarubber after drying the film, so that really the albumen only serves the purpose of providing a clean surface for the sensitive material to be spread upon. With a suitable pyroxyline, and this is not difficult to find, nothing more than polishing with powdered talc is at all needful.

YELLOW stains on negatives, making their appearance after a few months, appear to have been troubling some of our readers of late. At the meeting of the London and Provincial Association, reported on another page, this subject has been discussed, and a plan for removing such stains recommended by Mr. A. Cowan. It consists in first bleaching the negative with a solution of perchloride of iron and then applying the ferrous-oxalate developer, by which a black image will be brought out.

OUR New York contemporary, the *Photographic Times*, is issued this year with a new cover of a drab colour, which we like much better than any of its several predecessors. It is to contain weekly illustrations.

At a meeting of the Physical Society of Berlin some of the most remarkable photographic exploits hitherto achieved were recorded. Artillery projectiles in the act of flight, it is known, have been successfully taken, but as to the position of the shot at various portions of its career—that is to say, its vertical and horizontal deviations—nothing has been ascertained and nothing known. It occurred to Professor Treason to make the projectile itself the means of photographically registering the peculiarities of its own motions, and this he did by making a small aperture in its hollow conical end, and placing opposite to this aperture a photographic plate. The gun is then fixed point-blank at the sun, which, shining down through the little hole, sends on to the plate a tiny beam of light, whose direction is altered according as the shot points more or less away from the direct line of flight. The direction of the elongation of the image of the point into a line shows the amount and the direction of the deviation, while a rotary motion is shown by the point assuming the form of a spiral line. Negatives exhibiting these phenomena were shown at the meeting. America thus is proved to possess the largest camera in the world; but it has been reserved for Europe to achieve the feat of taking useful photographs in a pinhole camera travelling at the rate of a mile in a few seconds of time.

A CURIOUS property of iodine has been incidentally shown by a writer in the *Moniteur Scientifique*, namely, the decolourisation of its solution in alcohol by certain essential oils, and its unalterability by

others. Thus, oil of peppermint instantly decolourises the solution; oils of ginger and of juniper in a minute; oils of pepper and cardamon in two minutes; and oil of mace in from three to eight minutes. It was not decolourised at all by oils of coriander, carraway, turpentine, rue, saffron, rose, rosemary, orange, aniseed, fennel, angelica, or wormwood.

THE condition of the surface of the glass is a factor which is taken little account of in estimating the relative rapidities of lenses; but that it is by no means a negligible quantity, is shown by a paper by Sir John Conroy recently read before the Royal Society. He says it seems probable that the amount of light reflected by freshly polished glass varies with the way in which it was polished, and that it is sometimes more and sometimes less than that indicated by a certain theory. The amount of light transmitted is of course complementary to that reflected. Sir John Conroy says that the surface of polished flint glass seems to alter somewhat readily, the amount of the reflected light decreasing, and the amount of transmitted increasing, whilst with crown glass the change, if any, proceeds very slowly. He further cannot find any evidence as to the particular cause to which the changes are due.

THIS report, however, will be another timely reminder to every photographer of the necessity that exists for taking great care of the lenses he employs. They should always be protected from atmospheric circulation when not in use, as practically all bodies receive a deposit from the atmosphere when it freely circulates about them, no matter in what position their surfaces may be placed, and the repeated removal of this deposit by even the most gentle friction must eventually interfere with the integrity of the original polished surface, quite apart from any action such as Sir John Conroy describes. How often has not the thoughtful photographer been horrified to see a careless operator bring out from his waistcoat, or, mayhap, his coat-tails, the several members of his battery and lenses, and at once set to work to photograph after a preliminary rub with his handkerchief. Lenses so treated are bound to suffer eventually, when even such mild treatment as that whose repetition we have just deprecated may be fairly expected to result in injury.

THE *Chemical News* lately contained a very interesting extract from the *Contributions from the Jefferson Physical Laboratory*, by Mr. J. C. B. Burbank, in regard to the photographing of the invisible rays beyond the red of the solar spectrum by means of stained plates. He says, "The direct action of absorbents in the infra red has not hitherto been tried with any success; moreover, it has been stated by so eminent an authority as Captain Abney that it was impossible to make plates sensitive to any rays below the A of the solar spectrum by means of the addition of dyes to a film. It is true, however, that Major Waterhouse has succeeded by means of turmeric in obtaining evidence of the existence of a few lines on the less refrangible side of A; but in all cases except one they were reversed." Mr. Burbank, substantially following Mr. J. B. B. Wellington's plan, and using the very vague preparation termed cyanine with his plates, and working with Rowland diffraction gratings, found no difficulty in photographing from the A line to wave length 9000, or to the limit assigned by Captain Abney as the limit of the diffraction spectrum, none of the lines being reversed. There are cyanines and cyanines, and the achievements which were impossible at one time with then existing dyes, may be comparatively easy by the new materials offered by the march of invention; but, quite apart from any previous ideas on the subject, further interesting light is by this article thrown on the important topic of orthochromatic plates.

HOW I MADE AN ENLARGING ILLUMINANT.

I WAS much interested in the series of leading articles on *Enlarging for Amateurs* in last year's volume, especially in the so-called "makeshifts," which, if carefully and well constructed, are frequently deserving of a far better name, and actually remain for years as permanent adjuncts of the studio or laboratory. Such a "makeshift" I have had in use now for a considerable time—three or four

years—as occasion requires, in the form of a lamp or illuminant, for enlarging by artificial light; and as when not required for enlarging purposes it fulfils other, its legitimate functions, and is ready at the shortest notice for its newer duties. It may be at the same time described as a "makeshift" and an established institution.

Until the introduction of gelatine-bromide paper for enlarging purposes so greatly reduced the exposure, daylight was practically the only light by which ordinary photographers, especially amateurs, could enlarge; indeed, for the latter class enlarging may be said to have been really a closed pursuit. How different at the present day, when every exhibition teems with amateur enlargements, some, too, of the very highest quality. The increase of rapidity rendered possible the use of different forms of artificial light that were hitherto out of the question; and I well remember the surprise felt and expressed by others as well as myself, when, at a demonstration of enlarging at an hotel in the Strand, the work was performed by an ordinary paraffin lamp enclosed in a box glazed with ground glass. This was some eight or nine years ago I think, but who would nowadays wonder at such a performance.

Of course a proper enlarging lantern is the thing, but it is not every amateur who cares to go to that expense, while the ordinary optical lantern has but a limited application for purposes of enlarging, vignettes from quarter-plate negatives being about all it will effect. Daylight is much used by others as well as myself, but there are, of course, times when it is requisite to work at night, and then some method of evenly lighting the negative becomes a *sine quâ non*. Now this is a very easy, simple, and not a costly matter, but how few amateurs in comparison to the vast number there now are ever buckle-to and undertake the task. Many, it is true, are not amateur mechanics, and cannot rig up the necessary contrivance for themselves, even if they know what they want, which many do not. Others, again, have little spare space to cumber with additional apparatus, and amongst these I may reckon myself, and consequently they either deny themselves altogether the luxury of enlarging, or confine themselves solely to daylight, as I formerly did until I devised my "makeshift," which answers the purpose—that is the main thing—without necessitating any joinering operations, or occupying any additional room when not in use. It is true it is not in every amateur's household that the necessary material is found ready to hand, but where it is found that in procuring it it will fill two useful purposes at a small cost, the expense will frequently not stand in the way.

I may explain that my enlarging arrangement for daylight use consists of a long-bodied camera, carrying the negative at one end and the sensitive paper at the other, the lens occupying a variable position in the interior, the whole being adjustable for use either in the horizontal or in an inclined position, and it can be moved about the room in which I use it. I am thus fortunately placed in being able to use the same apparatus for daylight as for artificial light; for the latter purpose only requiring what I call the "illuminant," as being a better term than lamp or lantern. But with very slight alteration my arrangement of light can be adapted for use where the sensitive paper is not enclosed in a camera, but worked in the open room. The necessary modification I shall speak of later.

The basis of my "illuminant" consists of a Ripingille's portable heating and cooking stove of the upright square form, burning paraffin oil, with a wick about four and a half inches wide. Similar stoves are sent out by other makers, notably Wright and Butler, but the particular form or make is not of much importance, provided it fulfils the necessary requirements of having a broad wick enclosed in a metal casing with a glazed front aperture. Mine consists of an upright pedestal, square in plan, standing about twenty inches high, enclosing the lamp and reflector, and had originally a ruby glass front, calculated, I presume, to give it a warm and cheerful appearance when employed for heating purposes. The whole costs, I know, something under a sovereign, but exactly how much I forget, and is capable of comfortably warming a moderate sized room for a whole day with one filling of the reservoir, so that it is not a useless addition to the house if not often required for enlarging.

To adapt it for the latter purpose I first of all exchanged the ruby glass strips forming the front for similar sized pieces of plain glass. This glazing is absolutely necessary for the proper combustion of the

stove, as it completes the "chimney;" if the front be left open the lamp smokes badly and gives very little light. This glass is set back some inches into the body of the pedestal and close to the flame, so in front of that again, in the well-like opening, I fit a frame carrying a sheet of ground glass, or, better still, of oiled tissue paper, to diffuse the light. If the stove, so modified, be lit up in a dark room it will, however, be found to shed an abundant supply of light over the place, even when the front is covered up, owing to the rays that escape through the ventilating apertures. This matters very little, if at all, to me as I work, but for convenience' sake I place the stove in an empty case, *minus* the lid, the opening forming the front, and I find no difficulty about ventilation, as the open front sufficiently provides for that.

In the case of working in an open room the escaping light even from the front would prove fatal, but I would add to the arrangement in the following way; in fact I have long meditated doing so in my own case:—Pierce in the top and bottom of the back of the outer case several holes to supply ingress and exit for ventilation, and "trap" them with a piece of brown paper, dark cloth, or other material to shut off all light. Fit a door to the front having a square central aperture, with a ledge or support upon which to rest the negative; the front then becomes the negative holder at the same time that it shuts in all light, except what passes through the negative. If it be fitted with guides or runners after the manner of the sliding front of a camera, so much the better, for the negative can then be easily and quickly adjusted in position.

The affair is now complete, and all that remains is to gain a little practical experience in the best positions of diffusing screen, flame, and negative to secure the best and most even illumination. The reflection of the broad flame from the corrugated reflector and other portions of the polished metallic interior of the stove or lantern throw a beautifully even light on the diffusing screen, which suffices to light a half-plate or $7\frac{1}{2} \times 5$ negative. I am well aware that the illumination thus obtained is not of the highest class as regards rapidity, but it is certainly very good indeed for a "makeshift," and has satisfied me for some time. When operating on a dense negative I find I can gain a little more light for a short time by turning up the wick until the flame just smokes a little, but it soon burns down again to its normal light. The brief increase, however, is often useful.

ERNEST GRAHAM.

ECHOES.

I NEED scarcely refer further to the case of Pollard *versus* The Photographic Company than to express my satisfaction to find in last week's issue that more than one correspondent takes the same view as myself. With regard to Mr. J. Hubert's assertion that my "argument is as poor a one as could be advanced," because "the principal aim of such a society should be to convert" an uncertain law into a definite one, I can only say that if the society commenced by, or made a practice of, what another correspondent describes as "defending and justifying a wrong," I don't think it would gain sufficient support to enable it to do anything, let alone reform the law of the country. Its aim "should &c." Quite so. "I can call spirits from the vasty deep." "Yes, but will they come?"

My thanks are due to Mr. Bedding for pointing out my "stumble" in the attempt to pick him up. It is too often the fashion to blame such things on to the printer or "reader," but I do not consider that fair to either, and in the case of the latter, if he is to "query" every apparent slip in the copy that passes him, it assumes the possession of a general intelligence which few printing offices can boast of in their collective staff, much less in an individual. I therefore elect to set it down to carelessness on my own part.

In speaking of the "frequent" use of potassium chloride also, I may confess that perhaps my language "lacks the perspicacity that might upon reconsideration have been imparted to it," because if I had written "an alkaline chloride" instead of "potassium chloride" I should have expressed precisely what I meant. Ammonium chloride is no doubt generally employed, and is perhaps the best for the purpose; I myself most "frequently" use sodium chloride for no other reason than that it is usually the most convenient, and for the same reason, at the time, I have also used the potassium salt, but do not attach the

faintest importance, so far as intensification is concerned, to the base employed. The alkaline chloride is added simply to increase the solubility of the corrosive sublimate, for which purpose the ammonium is the most suitable. Whether any formula including potassium chloride has ever been published or not—and I think such a one is to be found—I shall not quarrel with Mr. Bedding on the originality of his discovery, but I cannot afford the time to wade through back literature to satisfy him. I may, however, offer a suggestion accounting for the absence of such a formula from both the publications he mentions; it is that probably neither the author of the one nor the numerous contributors to the other attach any more importance to the matter than I do.

But as Mr. Bedding invited, or rather "recommended," me to try his method, I thought it only fair to do so, and accordingly proceeded to republish his instructions. These I found ambiguous in the extreme; the strength of the solutions of mercuric chloride and potassium hydrate are definite enough, but how much of the latter to add puzzled me. It is to be added slowly in sufficient quantity to cause "turbidity," and "stopped the instant precipitation occurs," but above all an *excess* is to be avoided, as it would "ensure the formation of the yellow precipitate of mercuric oxide." Now I want to know how far "turbidity" may proceed before it becomes "a precipitate," and, further, I should like to be informed what constitutes an "excess," when, so far as I am aware, it is impossible to add caustic potash to mercuric chloride *without* precipitating the oxide? Then again, though the quantity of potash to be used is left beautifully vague, the absolute quantity of hydrochloric acid to be added to a given volume of a solution of variable contents is stated with mathematical exactitude, though, unfortunately, the value of this accuracy is somewhat lessened by the omission of all mention of the strength of the acid.

Now one of two things struck me as being absolutely necessary, either that the mercurial solution in Mr. Bedding's formula must be extremely acid and contain very little potassium, or else that it must contain very little mercury, for I found by calculation that to neutralise half a drachm of hydrochloric acid of the strength usually employed in photography about fifteen grains of potassium hydrate would be required, and that therefore each ounce of Mr. Bedding's "mercury-potassium solution" would contain three-quarters of an ounce of twenty-grain solution of potash, and a quarter of an ounce of the original twenty-grain solution of bichloride of mercury. A five-grain solution of mercuric chloride does not seem to me calculated to produce the accelerated bleaching action Mr. Bedding leads us to expect!

However, I went on to make the actual trial in order to test, as suggested, the comparative time occupied by the two methods. In one bottle a plain solution of chloride of mercury was made, in a second a solution of potassium hydrate, both of the strength given, while in a third twenty grains each of chloride of mercury and chloride of potassium to each ounce of water were placed, and the three were shaken up at regular intervals, each receiving the same amount of attention. I may say that the compound solution was complete in a little more than half the time occupied by the plain solution of bichloride, the former being *finished*, therefore, in half the time required for the *first stage* of Mr. Bedding's plan. That gentleman in moralising over the "stated solubility of many substances at, say, sixty degrees," &c., appears to have overlooked the fact that the potassium hydrate as well as the chloride has to be dissolved before it can be used; and that in making the mercurial solution in his way the bichloride *must* be dissolved *separately*, and, as a consequence, takes far longer. So much for the alleged advantage of celebrity; I need not say anything about the time that must be occupied in "dosing" the mercury with potash. But when, after dissolving the plain bichloride, I proceeded to add the potassium hydrate, I regret to say I got no turbidity—at least in the sense I anticipated from the description—nor even a "rapid formation of a white precipitate," as I was also led to suppose; but instead an *instantaneous* formation of the oxide of mercury as I had fully expected. This occurred with the first drop of potash solution, and certainly caused turbidity, but of the character, Mr. Bedding tells us, that is produced by the use of excess of potash; so that while anxiously awaiting further explanations, I must say that present evidence decidedly *contra* indicates the use of potassium hydrate in

the manner recommended since a single minim proves to be an "excess." The hydrochloric acid might just as well be used alone, but even then the brightness of the solution cannot be more perfect than in the mixture of the chlorides of mercury and potassium.

I am afraid it will be considered presumption on my part to venture to dissent from an editorial statement, but I must say I differ in my opinion from that expressed in the leading article on *Defects in Sensitized Paper* with regard to a certain photographer who "was never tired of inculcating the necessity of cleanliness of manipulation," &c., and who, the writer proceeds to state, he "knows" also practices what he preaches. The gentleman who leaves his freshly sensitized paper lying about on a table covered with old, and only "apparently" clean, newspaper with disastrous results scarcely, to my mind, deserves the unlimited confidence thus reposed in him. "Who generally practiced what he preached" would have been better, for in all ranks of life it remains true that *nemo mortalium omnibus horis sapit*.

Two valuable and suggestive articles on printing subjects have appeared from the pen of the veteran E. Dunmore—I use the term veteran not because he is "on in years," for I believe he is not, but on account of the length of time I have known his name as a contributor to THE BRITISH JOURNAL OF PHOTOGRAPHY. One point in his first article I do not remember ever previously to have seen emphasized, though glancing back mentally I cannot help thinking it is quite in accord with experience. I allude to the difference in the effect stated to produce by a *transparent* and a merely translucent yellow screen. It is difficult to explain why the clear glass should produce a better result in modifying an insufficiently dense negative, but that it is so in some cases at least I am certain. I had to produce a number of prints, some vignetted, from a portrait negative of such extreme thinness that it almost mastered me until I tried interposing a screen of glass coated with pale aurine varnish. The improvement was marvellous, at least with the "printed-out" proofs, but when I came to the vignettes, in the production of which an additional tissue paper screen was used, the effect obtained was, perhaps, worse than without the coloured glass, and the length of time taken in printing simply atrocious.

Without the colour a translucent screen does, in my opinion, operate favourably in modifying a thin negative, though this is denied by many operators or printers of experience, but it is certainly difficult to reconcile this result, if any view be correct, with that obtained in the case of the coloured screen. Mr. Dunmore's remarks also upon the effect exercised by coloured glass upon the tone of the print are also worth noting in connexion with the subject of pyro-stained negatives—the only evil effects being usually attributed to a stained film, an increased time in printing, and perhaps a "flattening" of the picture, or destruction of its brilliancy. But there can be no doubt the result reaches further, and probably more of the unsatisfactory prints one meets with nowadays owe that quality to the presence of pyro stain in the negative than to any other cause short of downright out-and-out bad manipulation.

Some years ago there was published, I think, in this JOURNAL—I do not remember the date precisely, but it was about twelve or thirteen years ago—a translation from a foreign journal of the account of some researches on the effect of coloured screens upon the tone of the resulting print. Captain Abney more recently has alluded somewhere to the same subject, which is one that would be well worth thorough investigation at the present time. Or, if not scientifically proved, it would be well if not printers only, but the operators who make the negatives, would bear in mind that the colour of the shadows of a negative, as well as the density of its gradations, exercise an influence in the final tone of the print that no modification of the gold bath will altogether overcome. Every one of the readers of this JOURNAL must have met with negatives from which it was almost impossible to make a bad print—so far as colour is concerned—and also with others which were equally incapable of rendering anything that could be coaxed or coerced into decent tone. Most frequently these are thin, feeble images which will not bear sufficient exposure to give a respectable deposit of silver in the shadows of the positive; but not infrequently they are of the class described by Mr. Dunmore as "yellow and slightly fogged," though all right as regards density.

The article by the same author on *Vignetting* in last number is also

worth reading, especially his remarks on vignetting landscapes, a practice that finds far too little favour, chiefly, I dare say, on account of its surrounding difficulties. With a *suitable* negative nothing is easier; indeed, it is then easier than the majority of portrait negatives; but, unfortunately, very few good landscape subjects will bear vignetting without a good deal of judicious "dodging." Still, the result, if the subject be a really suitable one, will well repay the trouble, and I think that vignette landscape would form a comparatively new field to be worked by artistic amateurs who have the taste, skill, and, above all, the time to devote to it.

By the way, while on the subject of vignetting, how unsatisfactory, as a rule, is the graduation of vignetted enlargements, especially those made by amateurs! I do not at all refer to the productions of some of the best professional enlargers, for these are difficult to improve upon; but even among the "pros" perfection is by no means general. This is not to be wondered at when the rough-and-ready method of vignetting is taken into account. Who will improve the method or let out, at least, part of the secret of how it may be done? Such a communication would be a valuable help to modern artistic work, especially among amateurs. JUNIUS.

THE COMMERCIAL ASPECT OF THE FLASH LIGHT.

[A Communication to the Glasgow Photographic Society.]

DOUBTLESS there are among you a goodly number who were present at the meeting of our Association which was held in these rooms rather over twelve months ago, and when I for the first time had the honour of bringing before the notice of the members of this Association, and, through them, to the great army of professional and amateur photographers of the rest of the world, the marvellous actinic power of light to be derived by simply blowing a few grains of magnesium powder, by the aid of an ordinary wash bottle, into a flame of common hydrogen or house gas.

No sooner had we, as an Association, considered this subject, and discussed the utility, for photographic purposes, of the extraordinary flash of light so derived, then nearly every Association throughout the length and breadth of the land followed in our footsteps and gave similar demonstrations.

Enterprising tradesmen also soon came upon the *tapis*, and before long offered to the public what has now come to be known as flash lamps for photographic purposes.

Into the many forms of these lamps or the various means employed to produce a flash of light of sufficient intensity to yield a fully exposed negative I do not, on the present occasion, think it necessary to inquire, for doubtless nearly all of you must be acquainted more or less with the different forms of these lamps as now advertised by so many makers.

They all, however, start from the point which we, as an Association, were the first to discuss, viz., the blowing of the magnesium powder into some flame or other, and so produce a flash of intense actinic light. In several instances I notice that attempts have been made to claim patent rights for such lamps, and quite recently I read in the columns of a photographic paper that a certain maker had actually prohibited others from employing an Argand burner for the purpose of yielding this light.

All I can say is, before I brought the public acquainted with the magnesium flash light I had experimented with an Argand burner, and gave over using it because I knew of a better means of getting the flash. But, gentlemen, those of you who are familiar with the flash light must be aware that at the outset, when we discussed and gave demonstrations at our last meeting, that we had to contend with a good many little difficulties and drawbacks which it was necessary to remove before it could *honestly* be said that such a means of gaining exposures was perfected. Some of these difficulties and drawbacks I promised at the time to endeavour to overcome, and to-night, along with our worthy treasurer, Mr. Bell, I mean to show you that such has really been accomplished, and that in such a manner as to make the flash light without doubt a commercial success.

When I say this I wish it to be distinctly understood that I do not include some of the ridiculous toys which the public have had placed before them during the year that has just passed away.

To my mind, if the flash light is to become of any practical value in the studio such must be lifted out of the category of an artificial toy, and made of such a character that exposures can comfortably be made with unerring precision in any studio.

In working out some ideas which struck me early last year I thought myself of what I once had the pleasure of witnessing in the

way of taking portraits on a very numerous scale by means of artificial light. I refer to the marvellous success which attended the efforts of the late Horatio Paterson, to whom was allotted the contract for photographing those who attended the last two calico balls which were held in Glasgow, and when I tell you that for several hours on end a constant stream of ladies and gentlemen eagerly pressed forward to have their portraits taken in all sorts of fancy costumes at St. Andrew's Hall (where Mr. Paterson had rigged up two studios in one of the ante rooms), and that on the occasion of the first ball somewhere approaching three hundred negatives were taken by artificial light, nearly every one of which were satisfactory to a very high degree, it struck me, when recently bringing to mind the *modus operandi* which Mr. Paterson employed on that occasion, that it would be a step in advance were I to work on similar lines with the flash light.

Into details of the manner in which Mr. Paterson had constructed his elegant little studios I do not think it necessary at this stage to refer further than merely remarking that he used as an illuminating compound a very dangerous mixture of chlorate of potash with other substances, and that the half tones in his picture were got largely by a clever arrangement of gas jets running round the entire room just somewhat resembling the footlights and wings of a theatre, the light from which was quite ample to allow of his focussing and posing properly previous to igniting the mixture in the lamp.

But some of you may say, "How is it, if Mr. Paterson was so successful on that occasion, that you do not now continue to advocate the use of the same means for securing pictures?" Such a question I grant would be a very natural one, and I shall at once answer it by saying, unfortunately for Mr. Paterson the highly explosive nature of the mixture which he used on the first occasion led to what might have proved a most serious catastrophe. As it was, the premises actually did take fire and the brigade had to be summoned. Luckily the mishap happened at the far end of the hall, when a large proportion of those who took part in it had left, and before the arrival of the brigade the efforts of those present was successful in overcoming the flames.

So much for the use of such a highly dangerous compound as was then and is still in use by some who make a speciality of artificial light.

Although I should never think of recommending any one to use this mixture, still, when recently considering this subject, I was forcibly struck with the simplicity of the lamp in which Mr. Paterson burned the compound. Such a lamp, gentlemen, you will see present to-night, and so, when Mr. Bell and I came to discuss the best form of lamp to experiment with, I unhesitatingly recommended him to try this one, and as luck had it we had not far to look for the same, for, hidden away in Mr. Bell's back premises we found the very thing we wanted, and which was doing duty as a cupboard in a dark room. It was not long before Mr. Bell caused it to be brought forth and done up with a little fresh paint, and now it looks quite a royal piece of apparatus.

So much for the past history of the flash light. I shall now proceed to explain to you a few of the experiments which Mr. Bell and myself have made.

I dare say most of you will remember that when I gave my first demonstration on this subject I used, in conjunction with the magnesium powder, a nice little lamp, which was actuated by clockwork, and burned magnesium ribbon. My reason for this was the necessity of having a penetrating light to get the sitter properly focussed; this little lamp did its work well, and answered the purpose for which it was intended admirably, but it gave off too much smoke, and was somewhat expensive.

Now Mr. Bell entered fully into the necessity of being able to comfortably pose and focus his sitters, and to him is due the credit of bringing in the aid of the limelight for this purpose. As an Association we are much indebted to him also for the untiring patience he has displayed in his studio in helping, with me, to bring this light to the state of perfection which you will see to-night. Not only has his studio been placed at my disposal, but he has spared no pains and expense in making our experiments a complete success. From the fact Mr. Bell and myself were singularly at one on the necessity of having some certain and reliable means of getting a sufficiently strong light to enable the sitter being comfortably posed and focussed, without such the enormous power of the flash light would be simply useless, for what would be the use of making exposures upon which no reliance could be placed for sharpness? We also claim further advantages by utilising the limelight in conjunction with the burning of magnesium powder.

In the course of the experiments which we made, we found that our exposures, when made with the hydrogen gas flame alone, did

not yield the same plucky results as when the limelight was being played on the sitter along with the flash. I account for this in the following way:—The flash light, when used in a certain manner, undoubtedly yields a broad diffused light, and seems to lighten up every nook and cranny of the room in which it is burned. Now we all know that in portraiture it is best to employ not only a good diffused light, but also at times a good strong side light, so as to bring up the high lights in contrast to the shadows and half tones of the face. In several of the experiments we made we noticed this result in a marked manner, and Mr. Bell will tell you that he has come to a strong belief that the best results can only be obtained when the two lights are burned in conjunction.

I know it may be argued that much could be done by allowing the flash light to fall on the sitter from a certain direction, so as it were to cast shadows on the face from the high points of the same, it must, however, be borne in mind that such a way of working would entail much more trouble in the studio; and I am also aware that there are those who, on theoretical principles, will argue and maintain that this verging of the lesser light of the lime jet into that of the more powerful one yielded by the magnesium powder in a sense completely overpowers the former, and therefore causes the same to be of no benefit further than yielding a general light of greater intensity. This may appear sound reasoning, but in the experiments which Mr. Bell and I made we formed a very strong opinion that a decided benefit was obtained when using them in conjunction. True, for a second or two previous to the flash the lens was opened on the sitter when only the limelight illuminated him, and this may have had some effect in assisting the high lights. The difference was, however, decidedly noticeable in the negatives we produced.

Be this as it may, undoubtedly the limelight answers most admirably for focussing with, and at the same time I believe helps considerably to bring up the high lights in the picture.

In the experiments which we made we used an ordinary blow-through, or as some choose to call it, safety jet, but with this marked difference, that immediately beside the nozzles of the jets we had an auxiliary jet of hydrogen gas, the flame from which was of the ordinary household type. This can be turned up or down just like an ordinary gas bracket, and it is into this hydrogen flame, along with the face of the lime, that we inject the magnesium powder by means of the wash bottle.

To Mr. Bell is due the credit of suggesting the addition of this extra hydrogen jet. In the course of our experiments we noticed also that such an arrangement seemed to yield far less smoke than when using a hydrogen flame alone, and that a very much better light is obtained when the lime is dusted and freed from any magnesia that may attach itself from a previous exposure. Mr. Bell considers this cleaning of the lime a very important point. Over the face of the lamp you will observe we have placed an arrangement which acts as a curtain, but in such a way that the same can be raised or lowered in such a manner as to throw more light on the drapery of the sitter if desired than on the face. The dimensions of the lamp are 34 x 30 x 12 inches, and to shield the eyes of the operator when blowing the powder into the hydrogen flame we have intervened a sheet of blue glass which allows him to see nicely how to direct the nozzle of the wash bottle and so work in comfort.

Later on, gentlemen, you will be invited to inspect the arrangements of the jets and the lamp, which is simplicity itself, and which could be made out of any old box with the greatest of ease.

Such, I think, lifts the flash light out of the category of a drawing-room or amateurist toy, and in the hands of any average operator in the studio is certain to yield regular and uniform results.

With regard to the other accessories which we used, these were just those in every-day use in Mr. Bell's studio.

To overcome the shadows the sitter must be so placed in position that the light does not throw the same on to the background. This is easily arranged for by slanting the background so as just to escape the shadow. We used an ordinary white sheet for a reflector thrown over and stretched on a three-panelled screen.

We had no smoke. This was got rid of by leading a funnel from the top of the lamp to a few inches under a little window in the roof of the studio. The construction of the lamp, you will observe, is such as provides ample ventilation for blowing the smoke out at the top.

We had not a particle of dust, what little there was never left the inside of the lamp.

We had no doors in the lamp to open for the insertion of the wash bottle, this was arranged for by only glazing the side of the lamp less than half way down, the bottom portion being quite open at all times.

Now just a word to those who may be unacquainted with the working of the limelight, and who, from what they may have read in the past, have formed some opinion that such is not a safe light

to work with. Without detaining you, gentlemen, with any long remarks on this point, I would just briefly state that, in my opinion, much of the prejudice which has existed against the use of this light, on account of some real or fancied danger, has arisen from some of the original drawbacks, such as the idea that the gases are used in a mixed condition. Such old-fashioned ways of working were discarded long ago, and with the blow-through jet it is impossible that such can occur. Then, again, the old-fashioned gas bags, with their heavy weights and pressure boards, and which took up so much room, are also things of the past, and in their place is used bottles with regulators which make the limelight simplicity itself, at the same time removing any little chances of danger which might previously have arisen. I consider there is far more danger to be apprehended from a common oil lamp than from a limelight jet at any time.

Then as to the expense of working the same. With gas, as it is now supplied in compressed bottles, either hydrogen or oxygen can always be kept in stock in any part of the country, and a few shillings will be ample to cover the cost of burning the jet continuously for an hour or so every night during the week, when not required the gas can be turned off.

Another important advantage which attaches itself to the use of gas bottles in place of bags, is the possibility of so erecting the lamp and gas cylinders upon the same stand, and when such is furnished with castors like an ordinary camera stand, the same can, with the greatest of ease, be moved about in the studio, such being impossible in the case of gas bags, or when the hydrogen is supplied from a gas bracket by means of a lengthy rubber tube.

With regard to the smoke, which it is necessary to provide for, at a very little cost a few yards of common wire can easily be made into the form of a spiral spring; and when the same is covered over with any suitable material, such as cloth or stiff paper, an extemporised funnel is the result, and one which will do all that is necessary to lead the smoke to some aperture in the roof of a studio, or the top of a window in an ordinary room. We have such an home-made article here to-night for your inspection.

I would just say, gentlemen, that Mr. Bell and myself will be very pleased indeed to learn of any lady or gentleman who are specially desirous of sitting for their portrait to-night. It is our intention on this occasion to confine ourselves to bust pictures, taking inch heads with the view of afterwards vignetting same.

We are much indebted to Mr. Mason for assisting us in furnishing our little studio to-night. He has, as formerly, kindly placed at our disposal all that we required in the way of background, &c.

So much, gentlemen, for what we hope to demonstrate to you to-night. As to the utility of the flash light, in my opinion, in the hands of a competent operator, it is capable of yielding most excellent results, far and away better than some who have a deep-rooted prejudice against artificial lighting are aware of. We all know that occasions will crop up—such as fancy dress parties, large dinners, balls, &c.—where, unless some means can be devised of taking the pictures of those present on the spur of the moment, as the saying goes, the opportunity is lost, and no photographing ever takes place. But when any one can arrange for a room to set up such a little studio as you see to-night, there need be no difficulty on the part of a professional undertaking to work at such times and places as I have stated.

T. N. ARMSTRONG.

COLLODIO-BROMIDE EMULSION.*

There are, doubtless, many amateurs who never saw a plate coated with collodion; it is very easy when you know how, but there is a slight knack or calculation about it that has to be acquired. Mr. Dunsterville thus clearly describes the process:—"After securely fixing a pneumatic holder to the back of the plate, dust the top surface with a flat camel's hair brush, and pour on the centre of the plate a pool of emulsion that will cover about one fourth of the whole area; now tilt the plate slightly so that the emulsion will run to the right-hand far corner, then to the left-hand far corner, then to the left-hand near corner, and finally pour off the surplus by the right-hand near corner into the filter; the plate should then be raised to an almost vertical position and rocked vigorously to and fro, to prevent marking or lines; when the emulsion is apparently set and no more drops from the plate, it may be put in a grooved rack to dry spontaneously, or laid upon a flat surface and dried by gentle heat, say 150° Fahr.

Mr. Brooks states that care should be taken to remove any hard particles from the neck of the bottle before coating, and that the plates should be placed an inch and a half apart on the drying rack, which may be set in any suitable cupboard. If they are set closer they will not dry evenly. The plates will dry ordinarily in about two hours.

Coming to the matter of exposure, we find a great difference between

* Continued from page 20.

these plates and the regular gelatine lantern plates; I should say they were from ten to twenty times slower, as, for example, in reducing by the camera. I used a Bausch & Lomb universal lens with nearly full aperture, and gave an exposure of six minutes at 3 p.m. with a fairly dense negative backed by a clear sky. In developing I found the plate was very much under exposed. I then made another exposure of twelve minutes on the same negative, the latter being illuminated by sunlight at 10 a.m., and obtained a fair slide, which, though I used a very weak developer, came out rapidly. In fact, it was considerably over exposed. Probably six minutes in sunlight, and perhaps four, would have been enough.

I would have given about a minute's exposure on the same negative, using the same lens stopped down to $\frac{1}{4}$ upon an ordinary lantern slide gelatine plate. Mr. Brooks advises an exposure in the camera from one to ten minutes or more, using a quarter-plate portrait lens of short focus at nearly full aperture. A long, full exposure gives warm tones, which can be changed to other colours by toning baths, but a short exposure gives cold tones, which cannot be altered by subsequent treatment. In the tropics, where the light is stronger, Mr. Dunsterville reduces a $6\frac{1}{2} \times 4\frac{1}{2}$ negative to $3\frac{1}{2}$ inches square, using a Ross' rapid symmetrical lens at full aperture, and a clear sky as background, at an exposure varying from two to six minutes. This emulsion is therefore better adapted for printing slides by contact than for reducing, though the latter can be done easily enough if one has the time to spare. In contact work the exposure varies from one to six seconds to diffused daylight; or from two to four minutes one foot away from a six-foot fish-tail gas jet; or the burning, about eighteen inches from the printing frame, of one inch in length of ordinary magnesium ribbon held in a pair of pliers. During the exposure the magnesium must be moved around in front of the frame to ensure even illumination of every portion of the negative. I tried the experiment of burning eighteen inches of magnesium in front of the negative. When I removed the plate, to my surprise a faint image of the picture was imprinted on it, which I successfully developed out by weakening the developer. Mr. Murray tells me he has brought such an image out by simply flowing the plate with the ordinary pyro solution. Sufficient ammonia was liberated from the plate to accelerate the action of the pyro.

Too much care cannot be exercised in handling these plates, as the surface is much more delicate than the gelatine plate. The negative must be carefully dusted with a flat camel's hair brush, and then the plate must be laid directly on the negative in the printing frame, taking care that while fastening the springs no sliding or rubbing action takes place. The springs may be considerably lighter than is usual. The least movement of the plate over the surface of the negative is apt to cause scratches.

The developer advocated as the best is alkaline pyro. According to Mr. Brooks it is prepared as follows:—

SOLUTION P.	
Pyrogallie acid	96 grains.
Absolute alcohol.....	1 ounce.

SOLUTION A.	
Saturated solution of carbonate ammonia	4 ounces.
Potassium bromide	1 drachm.
Soda acetate	2 drachms.
Water	12 ounces.

The carbonate of ammonia for the solution should be fresh and hard, and smell strongly of ammonia, otherwise it is of no account.

Four ounces of the salt are broken up and put in a twenty-four-ounce bottle, and eighteen ounces of cold water poured on it. The bottle is well corked, preferably with a rubber cork, and is then vigorously shaken. In twelve hours the water should be found to be completely saturated with ammonia and in a prime condition, and if kept in a dark place will last for several weeks.

On mixing the developer take of—

Solution A.....	3 drachms.
Solution P.....	5 to 10 drops.

It will be noticed that solution P has a strength of twelve grains of pyro to the drachm, so that ten drops (equivalent to ten minims), would represent two grains of pyro. The amount of solution P is very important; if the negative is very intense two or three drops will be found ample, and will give harmony, but the development will be somewhat slow; in extreme cases the developer may be diluted to twice or thrice its bulk with water. With an ordinary negative the full amount of solution P may be used. A glass dish is best to develop in, so Mr. Brooks advises; but I find it very easy to develop by holding the plate at one corner or by a pneumatic holder or manipulator, and ponring on and off the developer, having a tray underneath to catch any that may spill over. After exposure, pour over the plate from a bottle common alcohol three parts, water one part, and allow it to soak on the film for about half a minute, then immerse in a tray of clean water to soak out the alcohol; when the water blends with the film, pour off and apply the developer as previously stated. If properly exposed the image soon makes its appearance, and gradually but surely gains in intensity.

Mr. Dunsterville uses the same pyro solution, but substitutes for Mr. Brooks's alkaline, or A solution, the following, calling it No. 2 solution:—

No. 2.

Carbonate of ammonia	60 grains.
Potassium bromide	5 "
Acetate of soda	10 "
Distilled water	3 ounces.

Or instead of these the following:—

1A.

Pyrogallie acid	1 ounce.
Sulphite of soda	4 ounces.
Distilled water	9 "

Make faintly acid with citric acid.

2A.

Liquor ammonia	1 ounce.
Potassium bromide	2 ounces.
Distilled water	9 "

To make the developer he takes of—

Solution P	15 minims.
Carbonate ammonia solution	2 drachms.
Water	2 "

Or instead—

1A	40 minims.
----------	------------

Equal to 4 grains of pyro.

2A	10 minims.
Water	3 drachms.

If the plate is fully exposed, the developer may be diluted with another drachm or two of water. When there is any sign of a veil coming over the high lights at once wash off the developer and fix the plate, which takes place in less than half a minute, with a solution of cyanide of potassium—strength, twenty grains to each ounce of water; wash well by placing the plate in a large dish of clean water for about a quarter of an hour.

The potassium cyanide, as is well known, is a most deadly poison (two grains being a fatal dose), and it is not necessary to keep the dish containing this solution in the dark room. If the plate is well washed after developing it may be safely taken outside the dark room and dropped into the fixing solution, or the latter may be poured upon it and off, the plate being held by a pneumatic holder.

In this connexion I may as well state that hypo will fix just as well as cyanide, only it takes longer and also requires more time to eliminate it from the film by washing. Mr. Newton advises fixing with a solution of four ounces of hyposulphite of soda dissolved in sixteen ounces of water.

(To be continued.)

F. C. BRACH.

THE RICHMOND EXHIBITION.

We are now able to supplement our notice of last week by giving the remainder of the awards:—

AWARDS FOR LANTERN TRANSPARENCIES.

- A. 5.—Silver medal, 675, G. W. Wilson & Co.
- A. 5.—Bronze medal, 676, Woodbury Printing Company.
- A. 10.—Fry's Silver medal, 683, A. B. Dresser.
- B. 18.—Silver medal, 699, B. G. Wilkinson, jun.
- B. 18.—Bronze medal, 689, W. A. Greene.
- B. 18.—Extra Bronze medal, 700*, F. Howlett.
- B. 19.—Bronze medal, 702, T. H. Morton, M.D.
- A. 6.—Silver medal, 705, G. W. Wilson & Co.
- A. 7.—Bronze medal, 706, P. W. Edwards.
- Optimus Prize for best Lantern Slide awarded to B. G. Wilkinson, jun., 699, B. 18.

AWARDS FOR APPARATUS.

- Silver medal, Watson & Son, for their new Camera.
- Silver medal, Shew & Co., for their new Changing Box.
- Bronze medal, F. W. Hart, for his patent Flash Lamp.
- Bronze medal, W. Tylar, for his Current Producer.
- Bronze medal, Marion & Co., for Dr. Krugener's Book Camera.
- Bronze medal, Houghton & Son, for their improved Developing Stand.

AMATEUR PHOTOGRAPHERS' MEDALS.

- B. 12.—Silver medal, 151, J. Gale.
- B. 17.—Bronze medal, 462, L. Meldon.

Our Editorial Table.

THE LONDON BRIDGE DIARY FOR 1889.

London: Chas. Straker & Sons, King William-street.

CONTAINING as it does an unusually large mass of that class of information peculiar to almanacs, and which will ensure it a welcome space on our table, this Diary is profusely illustrated by full-page

phototypes printed from Husnik blocks, being scenes and buildings in and around London from G. W. Wilson's photographs. It contains, also, useful information to authors and publishers. Each page of the diary contains one week.

THE PHOTOGRAPHER'S DIARY AND DESK BOOK.

London: Wyman & Sons.

A USEFUL Diary, containing three days to the page. It is prefaced by a variety of useful matter and tables, such as ready reckoners for calculating income and wages, stamp and legacy duties, photographic formulæ, English sovereigns since the Conquest, the Corporation of the City of London, and other things worth knowing by photographers and the general public.

PATENTS COMPLETED.

IMPROVEMENTS IN PHOTOGRAPHIC CAMERAS.

No. 2352. EDMUND PHIPPS, 11, Breeze-hill, Bootle, in the County of Lancaster.—*February 17, 1888.*

THE invention relates to cameras, commonly known as reflecting cameras, in which the image is, for focussing purposes, reflected by a mirror on to a screen. The objects are to adapt such cameras for instantaneous work and to enable the operator to regulate the time of exposure of different portions of the sensitive film.

The first part of my invention comprises certain adaptations to the well-known form of camera in which the image for the purposes of arrangement and focussing is thrown upon a horizontal translucent screen placed on the top of the camera, rendering same well adapted for instantaneous work, and particularly applicable where the camera is of the kind known commonly as a "detective camera." For this purpose a box camera is usually employed, but the camera may be partly of the box form with the necessary arrangements for extension, whether by bellows or otherwise.

At the front of the camera is placed the lens, and at the back is the usual receptacle for the sensitive film. Hinged at the top of the back, or by preference to a sliding inner frame at the back of the camera, is a frame or board carrying a plane mirror. The mirror must be arranged so that when placed in position for arranging and focussing the reflecting surface (whether glass or metal) makes an angle of 45° with both the ground surface of the focussing screen and the sensitive film. The base of the mirror may conveniently be permitted to rest on a vertical projection at the bottom of the camera. Attached to the front of the mirror frame, and of suitable width, is a hanging flexible, or partly flexible and partly rigid, screen or curtain of some opaque material. I find black cloth or velvet answers every purpose. In this screen is cut an aperture in such a position that when the frame and mirror is moved from its position of 45° towards a horizontal position, the aperture will pass vertically behind the lens, so allowing the cone of rays proceeding from the lens to fall for a greater or less length of time upon the sensitive film, the lower portion of the opaque screen by the same upward motion acting as a shutter cutting off the rays of light when the exposure is effected.

It will be found advantageous to attach a small plate of some solid substance to the hanging flexible shutter and let the aperture referred to be cut in this plate. The flexible shutter, either with or without the plate referred to, must be so arranged as to always hang vertically from the swinging mirror frame. The vertical dimension of the aperture will be governed by the rapidity of the lens and sensitive film employed. If a plate (as above described) is employed a diaphragm allowing the dimensions or shape of the aperture to be altered at the will of the operator as hereinafter described may be employed.

It may be found advantageous in some cases to use a perforated plate as a diaphragm sliding vertically behind the lens aperture in grooves attached to the woodwork of the camera; in such case the sliding plate may be furnished with a projection so arranged as to be caught by the mirror frame in its upward motion, or by some mechanical contrivance whereby the plate with the necessary aperture will by the movement of the mirror be carried upwards in a strictly vertical direction immediately behind the lens aperture and so effect the exposure, the lower portion of the plate, or a flexible attachment thereto, acting as a screen shutting off the rays of light after the exposure is made.

To exclude any diffused light which may enter between the sides of the camera and the mirror frame, I avoid the use of solid sides to the mirror frame as being apt to produce vibration during exposure, and I adopt hanging screens or curtains of some flexible opaque material, or being partly flexible and partly rigid, attached to the sides of the mirror frame, by preference attached to the under side diagonally and parallel to the path of the cone of rays passing from the lens, or the screen may be in the form of fan-shaped bellows.

The upward movement of the framed mirror carrying the exposure diaphragm may be effected by hand, or if a rapid motion is required may be forced up by a piece of ordinary clock spring fastened to some internal portion of the camera and acting against the under part of the mirror frame, or may be drawn up by an elastic band attached to the end of the mirror frame and at the top of the camera, or by a weight attached to the mirror frame working over a pulley. I attach a small spindle at one side of the mirror frame towards the front, allowing it to pass through one of the sides of the camera, a slot forming the arc of a circle being cut in the camera to allow of its passage upwards. By this method it is open to the operator by the pressure of a finger on the projecting spindle to cause the mirror to move at a slower rate at any period of its upward course, thus by allowing the shutter to move upwards for about one-half the distance at a rapid rate, and by then gradually slowing its motion, the exposure given to the foreground of the picture will be greatly in excess of that given to the sky. When the framed mirror rests at 45° the projecting spindle is retained in position by a hook or like mechanical contrivance placed externally on the camera and so fixed as to be readily released in the so-called "detective" cameras which are usually held in the hand during exposure, and where a varying exposure is not deemed necessary the hook or other like contrivance for holding the spindle may be advantageously placed inside the camera (the curved slot in the side of the camera in such case being dispensed with), the hook being fitted with an arm projecting through the bottom of the camera enabling the operator to release the mirror.

Another part of my invention consists in the means whereby I can alter the shape and dimensions of the exposure aperture (in the diaphragm passing behind the lens).

To the plate referred to I attach on either side of the aperture a band of metal so arranged as to allow of the insertion of a thin strip of some opaque material between the bands and the diaphragm plate, thus enabling the operator to diminish the size of the aperture, generally to permit it to diminish gradually to one or other of the sides; thus if the exposure aperture is a square in parallelism and the strip is placed diagonally the exposure aperture will assume the shape of a right angled triangle, and accordingly one side of the plate will receive an exposure considerably in excess of that received by the other.

The claims are:—1. In a photographic camera a hanging flexible, or partly flexible and partly rigid curtains or screens, attached to a swinging mirror or its frame, substantially in the manner and for the purpose set forth. 2. In a photographic camera the several means hereinbefore described whereby the diaphragm containing the exposure aperture is caused to pass vertically behind the lens by the upward motion of the swinging mirror. 3. The combination with a photographic camera of a spindle attached to a mirror, or its frame projecting through one of the sides of the camera and working in a curved slot, substantially in the manner and for the purpose set forth. 4. In a photographic camera the combination of an adjustable plate working on the face of a diaphragm, with a swinging mirror, substantially in the manner and for the purposes set forth.

A LAMP TO BE USED FOR PHOTOGRAPHING BY MAGNESIUM LIGHT.

No. 8598. WILLIAM GUTTENBERG, 29, Triangle, Queens-road, Bristol.—
June 11, 1888.

A LAMP for photographing by magnesium light, consisting of a glass case composed of two parts, namely, the bottom and cover, so fitted that when smoke is generated by the ignition of magnesium powder inside the lamp the smoke does not escape until the lamp is opened. The magnesium powder is mixed with powdered chlorate of potash in the proportion of one of potash to four parts of magnesium, and for use is laid in a train on the upper surface of the ground glass bottom, and when the cover has been placed in position the mixture is ignited through a hole cut in one of the ends of the lamp and a glass door is slid over the hole to prevent smoke escaping. The duration of the exposure is regulated by the length of the train.

For taking portraits, the lamp should be suspended at a suitable height by means of chains attached to a strip of wood fitting on top of the lamp.

My invention consists of a lamp in which magnesium powder is burned in conjunction with chlorate of potash, gunpowder, or any other combustible mixture, for photographing by artificial light. It has sides, ends, and bottom (and top, if so desired, according to shape) of glass, and is composed of two parts. The one part being the bottom, which is a thick piece of ground glass, whereon a train of the illuminating mixture is placed for ignition. The other part being the cover for retaining the smoke generated by the ignition of the powder. The said cover is made of pieces of clear glass bound together with tin (the shape of the cover I am describing is that of an inverted V with ends fitted to the sides).

The piece of glass used for the bottom of the lamp has a wooden frame round it with a beading on the upper side of the frame, so that when the glass cover is placed on the frame, the upper part of which is covered with felt, the cover just fits outside the beading, making the lamp smoke-tight, or the wooden frame may be attached to the glass cover and the bottom ground glass can be made to slide into the frame after the manner of a drawer. In both cases a strip of wood, having an angular groove cut into it and two chains attached a suitable distance apart, in the middle of the strip of wood is placed on the apex of the lamp, and the chains are brought round under the lamp and hooked on the other side of the strip of wood. The lamp can now be fitted with any sort of loop attached to said strip of wood and suspended at any suitable height for use. In one end of the glass cover a semi-circular hole is cut in the middle of the glass where it sits on the wooden frame, and a sliding glass door is fitted. The purpose of this hole and door is to enable the operator to ignite the mixture and close the door, thus keeping the smoke generated from coming into the studio or room where the artificial light is used.

A tissue paper screen should be used between the lamp and sitter to soften the light.

Claims:—1. A lamp for photographing by magnesium light, having all sides made of glass, thus causing a radiation of light in all directions, so that an even illumination is given on the subject to be photographed. 2. A lamp for the above purpose composed of two parts so fitted that the smoke generated by the combustion does not escape into the room, thus enabling repeated exposures to be made without getting the image veiled by fog. 3. A lamp for the above purpose so constructed that it can be suspended in such a manner that the light falls on the sitter from the same directions as in daylight portraiture, so that no shadow of the sitter is thrown on the background. 4. A lamp for the above purpose, the construction of which admits of a train of the illuminating powder to be laid, thereby giving a latitude of exposure from one to any number of seconds according to the length of the train, so that the resulting light is not so sudden and intense, thus avoiding the consequent contraction of the facial or optic muscles caused by a flash light. 5. A lamp for the purpose stated the size and shape of which are immaterial. It is advisable not to make it smaller than twenty-one inches in length, seventeen and a half inches in breadth, and twelve inches in height.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
January 22	Great Britain (Technical)	5A, Pall Mall East.
" 22	Bolton Club	The Studio, Chancery-lane, Bolton.
" 23	Photographic Club	Anderton's Hotel, Fleet-street, E.C.
" 24	Burton-on-Trent	The Institute, Union-street.
" 24	London and Provincial	Masons Hall, Basinghall-street.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, January 10, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. Cowan presided.

The HON. SECRETARY announced the resignation of Mr. William Ayres, in consequence of prolonged illness, and expressed his (the Secretary's) regret at the information, Mr. Ayres being one of the oldest and most experienced photographers in this country from Daguerreotype days downwards.

By unanimous resolution Mr. Ayres was appointed one of the honorary members of the Association.

A question in the box asked, "Is there any means of decolourising a negative which has become yellow from supposed insufficient washing?"

Mr. J. B. WELLINGTON said that insufficient fixing was a more frequent cause of yellowness in negatives.

Mr. W. COMB knew of a case of the kind in which the negative grew more yellow with age.

Mr. P. EVERETT knew such yellowing to come on a year after the negative had been taken, and it was deepest at the end of the plate from which the washing water had drained.

The CHAIRMAN believed that most negatives were insufficiently fixed.

Mr. W. COLES thought that that depended much upon the presence of iodides in the plates. Bromide plates properly washed required less time in the fixing bath.

The CHAIRMAN said that one plan of removing the yellow stain would be to bleach it with perchloride of iron and then redevelop the picture with ferrous oxalate; a black image can then be brought out, and to any desired density. If, however, the original yellow extends over the whole negative the plan will not answer, as a veil will redevelop.

Mr. T. E. FRESHWATER exhibited an old-fashioned stand, very light, which he preferred to any other portable stand in his possession. It had no loose parts and had a folding top.

Mr. L. MEDLAND had had one in use for four years and had no fault to find with it. It had, he said, been made by Horne & Thornthwaite.

Lantern pictures by Messrs. Atkinson, Starnes, Medland, Hastings, and Wellington were then projected on the screen; those by Mr. H. M. Hastings had a rich brown colour, and had been developed with pyro; carbonate of ammonia, and caustic potash; those by Mr. Medland were detective camera pictures of animals in the Zoological Gardens.

CAMERA CLUB.

On Thursday, January 10, the one hundred lantern slides just received from America, in connexion with the international exchange, were exhibited for the first time. Sir George Prescott presided, and prior to the lantern exhibition called for any objects of interest which might have been brought.

The Secretary handed round some prints on ivory films, and also specimen of a one-bottle developer in powder form, introduced by Mr. Oldham of Eton, for development whilst travelling.

The circumstances of the lantern slide exchange were then referred to and the names of the societies included in the exchange were given. They are as follows:—Photographic Society of Philadelphia, the Cincinnati Camera Club, the New York Society of Amateur Photographers, the Philadelphia Amateur Photographic Club, the St. Louis Camera Club, the Pittsburgh Amateur Photographic Society, and the Chicago Lantern Slide Club. The pictures shown on the screen were received with much admiration, and the work proved to be finer than any yet received in the exchange. The average is high throughout, and some of the slides are extraordinarily effective in colour and general technique. *Elephantia Caves* and *A Moonlight Effect* are gems of transparency work.

Subsequently other slides by Messrs. Brownrigg, Lambert, Leventhorpe,

Charters White, Elder, Orton, and Hansard were shown. Mr. Brownrigg unlavished the exhibition of a very fine and varied set by humorous description. Some of Mr. Leventhorpe's slides were of exquisite colour and quality.

The subject at the Club on Thursday, January 24, will be *The Application of Photography to Meteorology*, when Mr. Marriott, of the Royal Meteorological Society, will give an address, and illustrations will be shown.

WEST LONDON PHOTOGRAPHIC SOCIETY.

An ordinary meeting of this Society was held on the 11th instant at the Addison Hall, the President occupying the chair.

After the disposal of the usual business, Mr. G. F. BLACKMORE read a paper entitled *Notes on Ferrous Oxalate Development*.

The lecturer said: With regard to the materials necessary for compounding the ferrous oxalate developer, he considered it was highly desirable that they should not be purchased in solution, and that they should be procured from a reliable source; and he hoped to show that the ability to compound the solutions was not exclusively vested in the dealers in photographic requisites. If the worker was without an accurate knowledge of the strength of the solutions it was impossible to develop a plate intelligently. Notwithstanding the fact that high authorities had recommended various additions to the ferrous oxalate developer, he found that simple solutions of neutral oxalate of potash, pure ferric-stallard protosulphate of iron, and bromide of potassium, were all the chemicals that were really essential. He recommended that a pound of neutral oxalate of potash should be put into a twenty-ounce bottle and boiling water added to nearly fill it. When the solution was cold it should be tested with litmus paper in order to see whether it was really neutral, because commercial samples were frequently alkaline, or in some cases highly acid; if neutral, half a drachm of sulphuric acid should be added; the solution was then ready for use. He had found if left alkaline that the solution appeared to deteriorate rapidly and throw down a white precipitate. If it were found to be acid it would be unwise to make further addition of acid, as that would cause an increased tendency to frilling; in that case it should be neutralized by the addition of carbonate of potash, a few grains at a time, and then the known quantity of acid should be put in. It was said that oxalic acid might be substituted for the sulphuric, but he had never used it. The iron solution should be prepared by putting half a pound of protosulphate of iron into a ten-ounce bottle, to which half a pint of water should be added; the bottle should be immediately shaken up vigorously and the water poured away, the object being to remove all trace of a possible yellowish powdery crust frequently found on some of the crystals; a slight film might take place, but it was more than compensated for by the superior results obtained. The water having been poured off, sufficient boiling water was to be added to nearly fill the bottle, the solution being then allowed to cool slowly, and when cold half a drachm of sulphuric acid should be added. With solutions prepared in this way a deposition of crystals would take place when the solution cooled, which showed that they were saturated. An ordinary ten per cent. solution of bromide of potassium would complete the list of solutions necessary for compounding the mixed developer. The deterioration of the ferrous oxalate solutions appeared to be hastened by being principally due, as was the case with other developers, to the oxygenizing effect of the atmosphere upon them, to impure water, to the use of impure or oxidized crystals, or to their being in an alkaline state when made. The visible indication of deterioration in the potash solution was a cloudy or murky appearance, and with the iron solution a yellow, rusty, turbid colour instead of a brilliant emerald green. The first case of deterioration might be effectually overcome by keeping the iron solution in a bottle with an orifice near the bottom (which might be purchased at the philosophical instrument makers) and drawing off the solution from below. In lieu of a cork a layer of pure tallow oil should be employed, which would prevent the action of the atmosphere on the solution. The potash solution was less liable to deterioration, but if any appeared it could be removed by filtration. The functions of the three constituents of the ferrous oxalate developer were probably well known, but he might state briefly that the potash was the density giver, the iron the accelerator, and the bromide performed the same duty as in other developers, namely, that of a restrainer. His own practice was to use very little bromide; he preferred to rely upon adding iron in small doses, and in no case should the iron exceed one-fifth of the potash; if more were added there was great risk of turning the developer muddy. Another fertile source of muddy developer was the dilution of the potash solution with water before adding the iron; if such addition was imperative the water should be distilled. It had been recently recommended in the photographic periodicals to shake the bottles before using. This he had no hesitation in asserting was exactly what should be avoided. The lecturer was sorry to have to fall foul of authorities, yet, having tested the matter, he felt bound to lay his conclusions before the members. It was particularly necessary to add bromide with rapid plates containing iodide. With regard to the development of underexposed plates, he was bound to confess that the ferrous oxalate developer appeared less trustworthy than pyro. The difficulty appeared to be in getting minute details out before the blanching of the high lights and distances, the only remedy for each case was the addition of a small quantity of hyposulphite of soda. The amount of hypo must be very small; for instance, one drachm of a mixture composed of one drop of saturated solution of hypo in half an ounce of water. An effective method of coating up details was by applying two or three fresh solutions to the same plate. This, however, was apt to cause green fog. The lecturer was bound to make this statement deliberately, in spite of the fact that so low an authority than Captain Abney had stated, in the seventh edition of his *Lustrations*, that "green fog is never seen when using ferrous oxalate which has not an alkaline reaction." [The lecturer handled round a negative developed with ferrous oxalate exhibiting a green fog.] The treatment of plates having received correct exposure was much the same as when using other developers, and the same expedients might be resorted to. A slight acceleration of the shadows might be obtained by gently rubbing the part with the finger whilst in the tray or by removing the plate and brushing on the backward parts. He sometimes applied the back of the hand to the glass side of the negative in order to slightly increase the temperature; this, however, involved the danger of frilling unless carefully performed. Another point in development was the question of the ability of rocking the dish or tray. Although that matter had been freely discussed, in his opinion the root of the matter had not yet been reached; it appeared to him to be correct both to rock the tray and not to rock it. The process of developing the negative had the effect of slowing the developer; that is, a chemical action was going on, and the solution was making an exchange with the chemicals in the film. If this were considered it would be evident that the parts of the plates most acted on by light would be most active in making the exchange, consequently, if the tray were left still the developer overlying the most active portions of the film would be acted upon most and that portion of the solution would become slower or restrained. At the same time the less exposed parts of the plate were also acted upon by the solution overlying them, and not having been contaminated, through rocking the tray, with the slower part of the developer, would be in the best condition to bring up density on those parts of the plate. The converse was also true, that continually rocking the tray very much helped to increase contrast. It was in cases of over exposure that the ferrous oxalate developer seemed especially valuable, as it was possible to restrain it to an almost unlimited extent without frilling. In regard to cost, it had often been objected that this developer was an expensive one, and he was inclined to agree with that opinion if the usual practice of throwing the used developer away was followed, but if a bottle was filled to the stopper with used solution it might

be, with a further addition of iron, used over and over again. Finally, he hoped that if his observations did not have the effect of causing the ferrous oxalate developer to be more extensively used, they would at least be useful to those who wanted occasionally to make use of the developer in keeping.

Mr. J. D. ENGLAND said that he did not think Mr. Blackmore had sufficient impressed upon the members the necessity of using distilled water. He had found that the air imprisoned in ordinary tap water quickly caused the iron solution to deteriorate.

Mr. FOXLEE stated that on the introduction of gelatino-bromide plates he first used the ferrous oxalate developer on account of the wet plate character of the negatives produced by it, but he quickly came to the conclusion that pyro was a better all-round developer on account of the greater latitude of exposure permissible with it. A professional friend of his, having an extensive business in South America, employed until quite recently the ferrous oxalate developer for all his work; if any of the plates were very long in coming up he dipped a piece of paper in the hypo bath and stirred up the developer with it, which was a practical though certainly not very scientific mode of working. The developer, after use, was bottled off and a little tartaric acid added; the old solution could then when added to a small quantity of fresh developer be used over again and worked well. Worked in this way it was an economic developer.

Mr. WHITING said the great charm of ferrous oxalate was its cleanliness and its non-liability to give green fog, although in that respect Mr. Blackmore had been unfortunate. He also thought in the matter of simplicity it could hold its own against pyro, and with correctly exposed plates would give good results. He much wondered at the disproportion of the various components of the developer in formulae given by different plate makers, and thought it would be better if they discontinued issuing formulae with the plate, it being understood that any standard formula would produce good results.

Mr. J. D. ENGLAND called attention to the fact that a very strong ferrous oxalate developer could be formed by dissolving precipitated ferrous oxalate in a saturated solution of oxalate of potassium.

The PRESIDENT remarked that there could be no question that ferrous oxalate was a very valuable developer for transparency work, but with regard to its use for developing negatives much would depend on the character of the plates used. With some plates (whatever might be the cause) he had found it impossible to get density with ferrous oxalate, but pyro gave good results. With a suitable plate and correct exposure, no doubt ferrous oxalate would produce a technically perfect negative, but those conditions were essential. He knew that one of the largest portraitists in London used the ferrous oxalate developer. His plan was to put all the negatives in a large tray and develop them together, the progress of development was watched, and the plates were taken out as soon as they had acquired sufficient density. But that was certainly not a mode of working which he should recommend any one to adopt. He reminded them that the late Jabez Hughes when asked what developer he was in the habit of using replied, "Branu."

Mr. J. A. HODGKINS was of opinion that although the ferrous oxalate developer was valuable for certain special purposes it could not compare, for general work, with the pyro developer, which he recommended to be used in ten per cent. solutions. He thought the powdery deposit occurring in the oxalate solution would not occur if distilled water were used in making the solution. Although he gave Mr. Blackmore credit for the ingenuity of his mode of preserving the iron solution, he thought if the solution were made freely acid with sulphuric acid it would keep well in an ordinary stoppered bottle. He considered it an imperative condition that the developer should show an acid reaction with red litmus paper. Plates of his own manufacture which both frilled and gave green fog with pyro gave clean bright negatives when developed with ferrous oxalate.

Mr. STERN mentioned that he had tried a system of development with ferrous oxalate after bleaching with mercury, which had been recently advocated, but without the success which the author claimed for the process. He thought it a good one, as the process of redevelopment was a slow one and could be checked at any moment.

Mr. BLACKMORE having replied, the proceedings terminated.

The next meeting will be held on Friday, the 25th instant, when Mr. Hodgkins will give an account of a visit to North Wales with the camera, illustrated by views in the optical lantern. Visitors are invited.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

This Club held its first annual general meeting on the 14th instant, when Messrs. H. Beckford, S. Bolton, F. Cherry, C. Baffery, and M. Sanders were elected members.

The report and balance sheet were read and adopted, from which it appeared that a marked degree of success has attended the Club's proceedings since its commencement in June last. It numbers forty-five members. During the half-year papers and demonstrations have been given as follows:—*Photography, Past and Present*, The President; *The Flash Light*, F. W. Hart, F.R.S.; *Eastern Slide Making*, E. T. Hiscock; *Tuning and Focusing*, W. Hart; *Micro-photography*, The President; *Phototypes*, F. W. Cox; *Optical Contact Printing*, E. T. Hiscock; *Enlarging*, J. Oakley.

The election of honorary officers for the ensuing year then took place, the following being elected:—*President*: Mr. J. Humphries, F.S.A.; *Vice-Presidents*: Messrs. Beckett and Hiscock; *Committee*: Messrs. F. W. Hart, T. C. Lathbridge, W. A. Lavanchy, J. Saville, J. Stewart, and H. Walker; *Secretary*: Mr. H. R. Martin; *Treasurer*: Mr. E. Seymour Paul.

Mr. Ernest E. C. Damant, 25, Granville-road, Strand Green.

The next meeting of the Club will be held on Monday evening, the 28th instant, at the Iron Room, Granville-road, Strand Green, N.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

The ordinary meeting of the above was held in the Free Public Library, Hamilton-street, on Thursday evening, the 10th instant,—the President (Mr. Paul Lange) in the chair.

Messrs. F. Atkinson, W. R. Beaton, H. C. Hitchmough, H. B. Sharpe, and Jas. P. King were elected as members.

The **PRESIDENT**, after a few introductory remarks, drew the attention of the members to a new feature in connexion with the Association, which had been introduced by the Secretary (Mr. S. L. Mackrell). It was a synopsis of a provisional programme of first practical demonstrations for each meeting during 1889 which will be printed in the form of a membership card, and will also act as a reminder for the members when away from home, for the use of dark rooms, &c. The following is a programme of the practical demonstrations:—*Enlargements on Bromide Paper and Glass Negatives; Paper Negatives; The Art of Retouching; Developing Platinum Prints—Hot and Cold-bath Processes; Transferring; Practical Hints on Lenses, their Uses and Advantages; The New Dry Etching Process with Magnesium Light; Practical Hints how to Manipulate the Lantern (By M.L.). Photo-micrography; Stripping Films.*

The **PRESIDENT** then read a translation which he had made from the report of the Vienna Exhibition on the English section.

Mr. H. WILKINSON exhibited two exceedingly good prints, 10×8, done by contact on bromide paper, one of which he had developed with hydroquinone and the other with ferrous oxalate. He contended that in his opinion the one developed with hydroquinone was equal to any platinum print.

Mr. WILKINSON showed a platinum print which he had made from one of his own negatives, but after a short discussion the President preferred to take a print in platinum type from Mr. Wilkinson's negative, and compare the same with the bromide prints at the next meeting.

Mr. F. N. KATON exhibited four transparencies made by contact from one negative and developed with the same solution of hydroquinone, exposures of which he had given being eight, fifteen, thirty, and sixty seconds respectively, the only apparent difference in the transparencies being a very slight tint of yellow in the skies of three and four.

A practical demonstration, *Enlargements with Anthony's Apparatus and Bromide Paper, and how to Produce Enlarged Glass Negatives with Enlarging Camera*, was then presented (Mr. Paul Lange), ably assisted by Mr. W. B. BEATON, who then proceeded with the President making an enlarged glass negative, 12×10, from half-plate transparency, using an enlarged camera for same, from which he had a most novel way of illuminating the negative. It consisted of a gridiron form of three rows of piping, about eighteen inches long, each row having three gas burners, and the whole being fixed on a stand perpendicular; the gas being conveyed through a piece of tubing from one of the brackets in the room. An exposure of twenty-five minutes was given. During the exposure of the glass negative Mr. Beaton made two enlarged prints, 10×8 and 15×12, from half-plate negatives on Anthony's bromide paper, which he also developed and fixed, using ferrous oxalate for developing. The prints when finished received much commendation from all present.

DERBY PHOTOGRAPHIC SOCIETY.

THE annual meeting of this Society was held on the 8th instant, Mr. J. A. Cope presiding.

The **HON. SECRETARY** presented his annual report and balance sheet, which showed the Society to be still in a flourishing condition.

Eight new members were elected.

The **CHAIRMAN** introduced to the meeting Mr. H. S. BELLSMITH (of the Eastman Dry Plate and Film Company), who gave a demonstration of the manipulation of the Company's stripping films, transferotype paper, bromide enlargements, &c., also showing and describing the use of their Kodak camera.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE monthly meeting of this Society was held in the Masonic Hall, Surrey-street, on Thursday evening, January 10. The chair was taken by Mr. B. J. Taylor. There was a good attendance of members.

The minutes of the previous meeting having been passed, a committee of management were elected to carry out details of the *conversazione* to be held on February 12.

Mr. ALFRED REYNOLDS then read his paper on *Platinum-uranotype and Mercur-uranotype* (this will appear in a future number), two new uranium printing processes. A large number of prints made by these processes were passed round, and were much admired for their fine detail and softness.

The annual lantern slide competition is arranged to take place at the next meeting of the Society, on February 5.

DEVON AND CORNWALL CAMERA CLUB.

THE members of the Devon and Cornwall Camera Club held a *conversazione* at the Freemasons' Hall, Cornwall-street, Plymouth, on Wednesday evening last week. The weather probably deterred many of the members from attending, but in spite of the storm there was a fair muster of ladies and gentlemen.

The rooms were tastefully and comfortably arranged under the superintendence of Mrs. Carnell and Mrs. Harrington Baker. Cameras and stands of various patterns and by different makers were placed here and there for inspection, and on a long table were shown shutters, lenses, roll-holders, &c. Particular attention was given to a very handsome eight by five stereoscopic camera, built by Perken, Son, and Rayment for one of the members, and fitted with a pair of Optimum lenses.

Mr. A. A. CARNELL explained the mode of using the Eastman roll holder, some dummy spools having been kindly given by the Eastman Company for the purpose.

Tylar's metal dark slides were also noted by many as being both serviceable and cheap.

Some excellent framed photographs, presented by Mr. J. H. Edwards, adorned the walls, and were much admired.

The difference in photographs of flowers taken by an ordinary and by an isochromatic plate was much commented on; these latter plates were strongly recommended for portraits in dull weather, some of the members stating that

they had tried them for that purpose, and that they were most useful when the person to be taken had a yellow or red tint in the hair.

An album of photographs in platinum type, from paper negatives of views in a chair, and an enlargement of a cat on Ilford paper from an Eastman stripping film, were objects of great admiration, and the latter, which was almost life-size, was quite equal to any direct print.

Some prints on Ilford slow bromide, Alpha, and Edwards's sensitised paper were also shown and favourably commented upon.

Mr. Carnell then photographed several groups by magnesium flash light. This new process excited much interest and amusement, the brilliant flash causing some of the ladies, who were engaged in conversation, to give a considerable start, but, of course, after the exposure had been made.

Messrs. Henry G. Phillips, R. A. Penrose, and F. Popplestone were elected members.

The next meeting will be held on the 23rd instant, when Mr. R. Murray will give *A Retrospect by an Old Photographer, with a Few Hints to the New Generation*.

IPSWICH PHOTOGRAPHIC SOCIETY.

THE first annual meeting of this young but flourishing Society was held at the Town Hall, on Tuesday evening, the 8th instant. Mr. J. Dixon Piper, the President of the Society, occupied the chair.

The Committee's report was read, and proved to be encouraging. Since its formation, in March last, the Society had made steady progress. The financial position of the Society was satisfactory. The Treasurer's account showed that up to December 31, 1888, the receipts amounted to 6*l.* 10*s.*, with payments of 4*l.* 4*s.* 4*d.*, leaving a balance of 2*l.* 5*s.* 8*d.* in the Treasurer's hands. There were still, however, unpaid subscriptions amounting to 2*l.* 5*s.*, and outstanding liabilities of over 3*l.* 8*s.*, so that there only remains a few shillings credit balance in the Society's funds.

The meeting then proceeded with the election of officers. The present President was elected to continue in that office for the ensuing year. Messrs. Mason and Cade were nominated to fill the post of Vice-Presidents, and a Committee of six gentlemen was also chosen. In re-electing Mr. Pringle to the post of Secretary, the meeting acknowledged the spirit and energy he had infused into his labours.

Mr. Wiggan exhibited a magnesium flash light, and he passed several negatives round as specimens.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE usual fortnightly meeting of the above Society was held in the Priory Rooms, Old-square, on Thursday, the 10th instant,—Mr. W. J. Harrison, F.G.S., in the chair. There was a very large attendance of members and friends.

Messrs. T. Coud, H. A. Dugard, R. Folland, T. W. Lloyd, Herbert Miller, A. W. Wills, J.P., and W. L. Wills, B.S., were nominated for election as members.

The remainder of the evening was devoted to a lantern display and a paper by Mr. A. W. Pumphrey on *A Tour in Italy and Switzerland*; some one hundred and fifty slides were passed through the lantern illustrating the same, and Mrs. Pumphrey kindly read her descriptive diary, explanatory of the slides and places visited, the pictures of Rome, Naples, Florence, Venice, and Pompeii being exceptionally interesting.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

AN ordinary meeting was held on January 11 at the Institute, Bexley,—Mr. Dresser, Vice-President, in the chair.

Mr. Rushton was elected a member.

Mr. HAWKINS, when exhibiting a number of stripping-film negatives, pointed out one great advantage in films, viz., the frequency with which natural clouds are secured.

The **SECRETARY** showed a bromide print developed with hydroquinone from which he could not eliminate a slight yellowness although several acid baths had been tried.

It was stated that this yellowness was caused by over exposure and could not be removed by any known method.

Mr. REFFELL showed the monthly *Album* of the "Argosy" Postal Club.

Mr. RUSHTON gave the members a short account of *Six Months in Switzerland*, illustrating his remarks by showing a fine collection of views he had taken. He recommended tourists to suspend the camera, &c., from the shoulders, only carrying the tripod in the hand; it could be used as an alpenstock. He also advocated the use of a half-plate camera, as it was possible to obtain plates on the Continent which would fit an English half-plate slide.

A discussion ensued upon various points in Mr. Rushton's paper.

The next meeting will be held on Friday, January 25, on which occasion the President, Mr. Pringle, will read a paper entitled *Practical Photography*.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

THE annual meeting was held on the 8th instant,—Mr. H. R. Procter in the chair.

The annual report of the Hon. Secretary stated that outdoor meetings had been held at Barnard Castle, Tynemouth, Bellingham, and Chollerford. Ten new members were elected during 1888; on the other hand, several had been lost through removal and resignation.

The Treasurer's report showed a balance of 3*l.* 19*s.* 5*d.* in hand.

The election of officers for the current year resulted as follows:—**President**: Mr. A. S. Stevenson.—**Vice-Presidents**: Messrs. J. P. Gibson and H. R. Procter.—**Council**: Messrs. M. Auty, J. Brown, T. Galloway, J. E. Gould, H. C. Hemy,

P. M. LAWS, W. PARRY, H. G. RIDGWAY, E. SCHUMANN, and L. WILLIAMSON.—*Hon. Treasurer*: Mr. J. W. ROBSON.—*Hon. Secretary*: Mr. EDGAR G. LEE, 3, Woodbine-road, Gosforth, near Newcastle-on-Tyne.

Six new members were elected, and a vote of thanks was passed to the Treasurer and Secretary for their services during the past year.

LEWES PHOTOGRAPHIC SOCIETY.

THE ordinary monthly meeting was held on Tuesday, the 8th instant, at the Glee Room, Cliffe. Mr. J. TUNKS, Vice-President, occupied the chair.

Special reference was made by the CHAIRMAN to a vote of condolence to the President (who had lost his wife) which had been passed by the Committee.

One new member was elected.

The subject for discussion—*Toning, Fixing, and Mounting Prints*—was then opened by Mr. G. FOXALL.

At the close of the discussion some micro-photographs were shown by Mr. P. MORRIS, prints toned with borax by Mr. E. FULLER and the Secretary, and negatives developed with hydroquinone.

It was decided that *The Making of Eastern Slides* should form the subject for discussion and demonstration at the next meeting, to be held on February 5.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

THIS Society commenced their winter session on Wednesday evening under most favourable auspices. Mr. S. W. ALLEN occupied the chair.

The lecturer for the evening, Mr. ALEXANDER KEILAR, delivered a discourse on *Photographic Optics*, describing the combination of a lens, distortion, depth of focus, width of angle, rapidity, relation between aperture and focal length, &c., illustrated by coloured diagrams. Arrangements are pending with the Cardiff Naturalist Society to obtain photographs of the neighbourhood which are worthy of permanent record, such as sections of rocky strata, large trees, old monuments, &c.

The next lecture, on *Hydroquinone as a Developer*, will be given by Mr. C. H. MANUEL, on the 23rd instant; and on the 30th instant Mr. ALBERT LIMBEN will give a lantern exhibition of Brazilian scenery.

Following up the example set by the Camera Club, the Society have decided to hold a few "one man exhibitions" in their commodious studio, Mr. W. H. KITCHIN, who was favourably noticed at their recent exhibition, being the first exhibitor.

Those wishing to join the Society should communicate with the Hon. Secretary, 127, Bute-road.

BRECHIN PHOTOGRAPHIC ASSOCIATION.

THE ordinary monthly meeting of the above was held on Wednesday evening, the 9th instant, in the Mechanics' Institute.—Mr. SCOTT, jun., Vice-President, in the chair.

Messrs. FERRIS, KERR, and WILLIAM DAKERS, were admitted members.

Mr. WILLIAM JAMIESON read a paper on *Apparatus*, and showed and explained an Eastman's roll holder and new Kodak hand camera lent for the purpose by two of the members.

Dr. ANDERSON, in a racy paper, strongly recommended those who took only small negatives to go in for enlarging, the Association's lantern being very suitable for that purpose. Thereafter he gave a practical demonstration of how it was done, a very good enlargement in brown of the *Boy n' Dog* on Eastman's permanent bromide paper being the result.

A vote of thanks to the Chairman brought to a close a most enjoyable meeting.

At a meeting of the Council Mr. FOOTE-BROOMLEY was unanimously elected an honorary member of the Association.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE fourth general meeting of the session was held in the rooms, 207, Bath-street, on Thursday, the 10th instant.—The President, Mr. WILLIAM LANG, jun., F.R.S., in the chair.

The minutes of last meeting were approved, and Messrs. WILLIAM A. BROWN, WILLIAM GEMMILL, JAMES G. MAINS, FRANK MACKENZIE, and MATTHEW MCKENZIE, were elected members of the Association.

The PRESIDENT gave a short address, wishing the members success in 1889, which, he reminded them, was the Jubilee year of photography.

After some discussion, it was agreed to devote part of the fund left in trust by the old Glasgow and West of Scotland Photographic Society to the purchase of a first-rate optical lantern for the use of the Society.

Mr. JOHN ARNAY then exhibited prints from some reversed negatives, which he had obtained by exposing a plate under the original negative sufficiently long to cause a complete reversal of the image. Some of the reversed prints shown were quite equal in quality to the originals. The exposure required was about three hundred and fifty times that necessary to obtain a positive. The developer used was weak in ammonia and bromide and strong in pyro, and was composed approximately of six parts of ammonia, three parts of bromide of ammonium, and twelve parts of pyro, to one thousand parts of water. The exposure permitted considerable latitude, and, practically, was found to be from forty-five to sixty minutes at six inches from a No. 5 gas burner, or from fifty to eighty seconds to diffused daylight.

Messrs. T. N. ARMSTRONG and GEORGE HILL gave a joint demonstration of a flash light which they had worked out together [see page 38]. It consisted of an oxyhydrogen limelight with an extra hydrogen flame through which magnesium powder was blown from a wash bottle. The whole was enclosed in a glass case with a chimney to carry off the fumes. Several practical experiments were made with most satisfactory results.

Correspondence.

Our Correspondents should never write on both sides of the paper.

JANUARY MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—CONGRATULATIONS, &c., FROM A FOREIGN SOCIETY.—NOMINATION OF JUDGES.—A NEW LENS.—M. GUILLIMINOT'S PRESENTATIONS.—A NEW DEVELOPER FOR SILVER CHLORIDE PRINTS.

THE Photographic Society of France held their monthly meeting on Friday evening last, the 11th instant. This meeting had been postponed one week, on account of the New Year's holiday. M. DAVANNE was in the chair. A letter of congratulation, sent from the Photographic Society of Moscow to their colleagues of Paris, was read by the Secretary. A bond of union must be established between the two Societies, &c. The President of the Moscow Society was unanimously elected honorary member of the Photographic Society of France.

Voting was carried on for the nomination of the judges who will distribute the different awards in the competitions now on hand. Judges for Optics were elected: Messrs. BORDET, CHARDON, JANSSEN, LONDE; Commandants FRIBOURG and MOESSARD; the Colonels SEBERT, VIDAL, and WOLFF. Judges for M. Gaillard's Prize: Messrs. ANDRA, BALAGNY, BARDY, GOBERT; Commandants JOLY, LEMERCIER, and VILLECHOLE. Judges for Photographic Positives: Messrs. ANDRA, BALAGNY, CHARDON, HAINQUE de St. Serroch and LEVY.

The Photographic Society of France were about to organize a large show of photographic prints, but, in consideration of the forthcoming Universal Exhibition of 1889, it was thought wise to forbear.

A novel kind of lens was presented by M. SERMAISE. This lens is intended to take part in the forthcoming struggle for fame, as it is entered in the competition for Optics. The lens, instead of being of tint and crown, as transparent as possible, is cut out of blue and yellow glass. The inventor thus endeavours to do away with the coloured shades when orthochromatic effects are required. The idea was received as good and novel, but time will show if or not it is useful in practice.

M. GUILLIMINOT presented a number of sheets of zinc perforated in the centre. The oval hole is at the same time pressed upward by means of a die. These plates render great service in producing photographic busts, &c. Their low price will put them in the hands of all. M. Guilliminot at the same time presented some gelatino-bromide of silver plates so prepared that, after development, fixing, and the other manipulations, the film will rise from its support with the greatest ease, which is a valuable quality for those who print photographs mechanically. The film, it is said, is very firm, will not extend or contract, and will resist even hot water.

M. RAYMOND presented a new developer for positive prints, with which it appears excellent tones can be obtained.

SOLUTION A.	
Distilled water	150
Potassium bromide	2

SOLUTION B.	
Distilled water	100
Chlorhydrate of hydroxylamine	4
Alcohol	50

SOLUTION C.	
Distilled water	100
Ordinary carbonate of soda saturated to 36°	50

In order to develop proofs which have been obtained on paper prepared with silver chloride the manipulator must take—

Water	100 parts.
Solution A	3 "
" B	4 "
" C	5 "

Several presentations were passed over to the next meeting; the members being under the influence of the holidays, very little was seen or done.

PROF. E. STERNING.

OWNERSHIP OF NEGATIVE.

To the Editor.

SIR,—Perhaps you will allow me to draw the attention of photographers generally to the last paragraph of Mr. W. E. Debenham's letter in your last issue. The paragraph is suggestive and of present importance to every business photographer.

"If it could be supposed, which appears to me exceedingly improbable, that the ruling of Mr. Justice North can be disturbed, and the contention of the defendant that a photographer is at liberty to make what use he pleases of his customer's portrait were to be established, there would, in all probability, arise such an outcry from the public, that legislation injuriously affecting the photographer's rights might be speedily looked for. In this view, the success of an appeal in the case of Pollard *versus* The Photographic Company would be the worst misfortune that could happen to photographers."

The correspondence which has appeared in your columns respecting the ownership of the portrait negative shows that many of the writers are ignorant of the law of copyright. Let me tell all such that a copy of the law may be had for fourpence from the Queen's printers; and in an article in *The British Journal of Photography Almanac* for 1869 it is carefully explained by Mr. Le Neve Foster, a barrister, and, if I mistake not, one of the framers of the act. Mr. Foster was a distinguished amateur photographer, consequently understood the nature of a negative.

The custom of the trade has been mentioned by some of your correspondents—well, custom is said by some to be unwritten law. For this custom among our best photographers I would again draw the attention of photographers to the excellent letter of Mr. Debenham. He writes:—

"The customary proceeding and understanding amongst photographers with regard to possession and use of the negatives of private sitters is one which has the sanction of many years, and will, I believe, be found to be in accordance with common sense, and for the most part with such judicial decisions as have been given in the courts of law. It may be briefly stated as follows, of course supposing that no special arrangement has been made:—

"The negative is the property of the photographer, who has, however, no such copyright in the work as to prevent the sitter from having any kind of copy made from the prints with which he may have been supplied.

"The use of the negative is joint. The sitter cannot, of course, print from it without the photographer's consent, and the photographer has no right to do so without the sitter's consent."

To this I would add that in your issue of March 19, 1886, the writer of a leading article says, "When an artist is paid for taking a portrait he has no moral right to the negative for any purpose of his own. He has been paid for his work, and there is, or ought to be, an end to the transaction."

With a copy of the law for fourpence, and it so ably explained by Mr. Le Neve Foster, the custom of trade so clearly given by Mr. Debenham, and the substance of the law so briefly stated by the writer in the *Journal*, no photographer need break the law in ignorance, and breakers of the law are enemies to the profession.

I therefore suggest that all who are not satisfied with the law as it stands give in the *Journal* their objections to it, and state what alterations they propose should be made, that their alterations may be seriously considered by our business men, and thus prepare us for the time when alterations are proposed from outside the profession.—I am, yours, &c., J. T.

January 14, 1889.

To the Editor.

Sir,—I am sure you will allow me a space in your valuable paper to explain the case "*Pollard versus Photographic Company*," being myself the defendant in the case, and because most of the reports about this case are entirely wrong.

Mrs. Pollard and family were photographed at our establishment, and, according to her own statement, received every satisfaction. The photograph of herself was exhibited in the window in the usual way, also two of her children, all in cabinet size. The two children were painted in oils for specimen purposes only, and during the time that those portraits were exhibited the lady visited the establishment on several occasions. One day she called in and wanted to inspect the two cabinet portraits of her children which were in the window, and between which was placed her own portrait. The photographs were taken out and shown to her. She liked them so much that she ordered a couple of them, after which they were placed again in the window. Now, although she must have seen her own portrait at the same time, she never gave us the slightest hint that she objected to it being exhibited; in fact, we had every reason to believe that she did not object. This was about September. In the beginning of November I printed another copy of Mrs. Pollard, with "A Merry Christmas and a Happy New Year" on it, from one of Mariou & Co.'s paper negatives, and exhibited as an ordinary specimen in the window, certainly not thinking for one moment that this could in the slightest degree offend, knowing that she had not objected to being exhibited. (One photograph only was printed in the Christmas style, and certainly not offered for sale, nor ever intended for such. One evening a gentleman called to ask if he could buy the photograph in question, and was informed the photograph was not for sale. However, he particularly wanted to buy that portrait, and accordingly was asked if he had the right to do so. I asked him three times distinctly, "Are you sure you have the right to purchase?" and he declared in an emphatic way, "Decidedly I have." Taking his word as a gentleman, I sold it to him in good faith.

This was the only photograph sold, and, I consider, was sold to the lady herself, because she really sent him to purchase same. Now, tell me where is the wrong done? I never for one moment gave our solicitors to understand that we claimed the right to do with the negative what we liked; on the contrary, we distinctly informed them that if she had given us the slightest hint of her objections, we should have been too pleased to remove it at once; our counsel simply said that we had the right of making use of the negative for specimen purposes as long as we did not do anything unlawful, and as long as no objection was raised by the person. Now, I ask, is there a photographer in the United Kingdom

who has not done the same thing over and over again? We wrote to our solicitors to ask why the plaintiffs applied for an injunction and put us to unnecessary expense, when they might have requested us to abstain from exhibiting the lady any more. I hope that this explanation will be satisfactory to all your correspondents, and surely it justifies the letter written in such a patriotic way by Mr. Hubert. There are other matters I could mention which would still more prove that our dealing was strictly honourable, but, as the defence did not go deep enough into these matters, I am obliged to keep silent. I think the case concerns every photographer and should be supported by all, as it is only what might happen to-morrow to any one in the profession. I may add that an extension of time for the appeal has been granted.—I am, yours, &c., W. C. Bax, Manager.

Photographic Company, Rochester.

To the Editor.

Sir,—I am quite sure that when Mr. Debenham thinks fit to make a statement he knows what he is about; and taking into consideration the kind way in which he makes his attacks, one can scarcely fail to forgive him for a slight oversight which however, unfortunately, tends to do me an injustice. To explain this to him thoroughly in these columns is, to my intense disappointment, impossible. Suffice it then to remind him, and "Junius" in *Echoes*, that I stated distinctly that I thought it wrong to contend that the photographer could make what use he pleased of a negative; and, furthermore, that in the case cited an implied permission existed, because of the plaintiff's wife visiting the establishment for months, being fully aware of the exhibition of the photograph.

But why create a dispute about the matter, and endanger so important a project which Mr. Debenham himself strongly advocates? Even if the case "*Pollard versus The Photographic Company*" seemed uppermost in my mind, a careful perusal of my original letter proves that I had other cases besides this one in view when I urged such a scheme. For instance, the sentence "Photographers will probably have to part with a valuable negative to an amateur friend," &c., evidently refers to the case "*Marston versus Barnes*."

I own that I ought to have expressed this more clearly; but pressure of business prevented me from going deeply into this matter, as it has prevented me from attending at our several society meetings, which I scarcely need say is a punishment to me.

No sacrifice, however, I shall deem too great to assist in bringing about the great work of a union amongst photographers; and I rejoice to think that to conclude from the general tone of Mr. Debenham's letter his valuable patronage will practically be assured, whilst judging from his interest in photographers, and the able exposition of the law as related to the art, Mr. Debenham's brother would be an important help in the organization if his aid could be procured.

Once more I earnestly ask my colleagues to co-operate heartily to bring about the early formation of the society; which will then be prepared to meet a case when it presents itself, besides acting as a caution to malicious and reckless litigants.—I am, Yours, &c., J. HUBERT.

238, Mare-street, Hackney, E.

P.S.—With regard to what Mr. S. J. Debenham says about the copyright being vested in the sitter, I have always understood that the same is vested in the operator who actually takes the negative, a special assignment being made in the case of such operator not being the proprietor of the business. Of what use would this arrangement be if it belonged to the sitter? However, not having read the Act, I may be wrong.

COLLODIO-BROMIDE EMULSION.

To the Editor.

Sir,—I have just read in the last issue of *THE BRITISH JOURNAL OF PHOTOGRAPHY* a communication that was read at the Amateur Society in New York by Mr. F. C. Beach. It is entirely without foundation as to its being, as he states, a formula given by me to Mr. F. Dunsterville, and I know nothing whatever about it in any way, and I trust your readers will not be misled by such a statement, as every one will know, with the least grain of sense, that a manufacturer of collodio-emulsion for so many years, like myself, would not give my formula to a client, more than Messrs. Wratten & Wainwright or Messrs. Mawson & Swan would give the formula of the plate-making to their customers. I look upon the formula that Mr. Beach quotes as mine as most ragged in the extreme.—I am, yours, &c., Wm. Brooks.

Reigate, January 14, 1889.

HYDROQUINONE.

To the Editor.

Sir,—In your issue of the 9th November last you give prominent space to a leading article entitled *Permanent Hydroquinone*, and speaking in favour of a new form of hydroquinone offering the advantage of permanency.

This so-called permanent hydroquinone is described as of lemon colour and manufactured by Dr. Byk.

Your article has attracted attention in photographic circles in Germany, and the *Photographische Wochenblatt* recently brings the report that an analysis has been made of this hydroquinone by independent chemical authority with the result that this lemon-coloured product can no longer be described as hydroquinone, it being a mixture of hydroquinone and several per cents. of sulphurous acid. It is a well-known practice of all those wishing to prevent a change in a solution of hydroquinone to add sulphite of soda, which gives exactly the desired result. In the interest of pure chemistry it is not desirable that a mixture of hydroquinone and sulphurous acid should any longer be termed hydroquinone, which in its properly pure state is a chemical body most delicate to keep, and least of all can be termed permanent in solution. It is for the operator to mix his ingredients at will, but it would be dangerous to term chemical mixtures by the name of that chemical of which there is the larger proportion present.

Trusting that, in the interest of chemical purity, which is so essential to the photographer, you will be good enough to give space to this letter in your next issue.—We are, yours, &c., A. & M. ZIMMERMANN.

6 & 7, Cross-lane, St. Mary-at-Hill, London, E.C., Jan. 14, 1889.

[The sample of "permanent hydroquinone" upon which we reported was perfectly neutral, so could scarcely contain any free sulphurous acid, though the latter may have been employed in the process of manufacture.—Ed.]

SULPHITES.

To the Editor.

SIR.—The sulphites are very interesting, but they have one drawback—at least sulphite of soda in combination with pure carbonate of soda, that at a very low temperature it crystallises solid at bottom of bottle. I always use Platt's developer winter and summer, and get fine negatives (THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, 1886, page 199).

Water (hot or cold)	8 ounces.
Carbonate of soda (pure)	13 drachms.
Sulphite soda	6½ "

Carbonate potash same quantities.

Now it has occurred to me that if meta-bisulphate of potash be used, say 2½ drachms in each 8 ounces of water to 13 drachms carbonate of soda or carbonate of potash, from the sulphurous acid contained therein it would keep much better, though after a lapse of three or four weeks the carbonate of potash throws down a flocculent deposit. I always use my pyro dry—8 grains to the ounce. I have half a gross of small, thick, wooden boxes: 3 dozen contain 30 grains pyro each; 3 dozen contain 20 grains each—this answers for whole-plates. 20 grains to 6 ounces of water with half a grain of bromide of ammonium and 30 grains to 10 ounces of water for 12 × 10 plates, with same quantity of bromide ammonium, and in every case I get fine clear negatives like wet plates. But then I have a special mode of development. I use Rouch and Mall's plates, and rarely spoil one. I should like to have some opinions on the meta-bisulphate of potash as against the sulphite. With ammonia the former gives inky tones, with soda and potash clear, delicate, pinky brown, full of half tone.—I am, yours, &c., HARDING WARNER.

The Hollies, Clyde Park, Clifton, Bristol, January 5, 1889.

THE OLDHAM PHOTOGRAPHIC EXHIBITION.

To the Editor.

SIR.—I notice a letter on the above subject in your last issue which I cannot allow to pass without a few words in reply.

Mr. Mackie appears to be under the impression that the exhibition was promoted by the Oldham Photographic Society. This is not so; but, by the Free Libraries Committee. This Committee requested the assistance of the Oldham Photographic Society in getting together the exhibits, the arrangement of lantern lectures, and many other matters too numerous to mention here. The Council of the Oldham Photographic Society willingly assented, and the success of the exhibition is, in a great measure, due to their exertions.

The hanging of the pictures, however, was not done by the Oldham Photographic Society, but by the officials of the Free Library, and I certainly agree with Mr. Mackie (and many others who have complained) that it is a splendid example of the bill-stickers art. No wonder that the judges themselves were confused!

A series of evening lantern lectures were arranged by the Oldham Photographic Society to be given by gentlemen well acquainted with the subjects they undertook, and these lectures soon proved to be a great success. No sooner, however, did the gentlemen of this Library Committee (or at least some of them who had the management in hand) perceive this, then they began to arrange a number of other evening

lectures, without any intimation to the gentlemen of the Oldham Photographic Society, who had already arranged a syllabus. For what reason is best known to themselves.

These latter lectures are, no doubt, what Mr. Mackie alludes to, as these same lectures were simply sixpenny readings—descriptive of commercial slides.

I deeply regret that the Oldham Photographic Society ever allowed their name to be used in connexion with an undertaking where stupid bungling has been so apparent.—I am, yours, &c.,

A MEMBER OF THE O. P. S.

TAYLOR'S (NOT DALLMEYER'S) NEW DIAPHRAGM SHUTTER.

To the Editor.

SIR.—In a recent issue you described a new diaphragm shutter patented by Messrs. Dallmeyer & Beauchamp. The patent is No. 5619, of 1888.

This invention is wholly mine, having been explained by me in February, 1888, to Mr. Dallmeyer, who then said it was no use, the Waterhouse stops being preferable.

I heard nothing more of the matter until I read the specification in your paper, from which you will observe the application is dated April 16, 1888.

I immediately wrote to Mr. Dallmeyer for an explanation, but no explanation is forthcoming.—I am, yours, &c.,

C. PURCELL TAYLOR, C.E.

3, Kenton-street, Russell-square, W.C., January 15, 1889.

[Has Mr. Purcell Taylor publicly shown or described the shutter anterior to the date of the application for the patent?—Ed.]

A SUGGESTION TO ADVERTISERS.

To the Editor.

SIR.—Photographic makers frequently note in their advertisements, "Catalogue sent post free on application, or on receipt of so many stamps."

That doubtless applies to England; but if they would add in their advertisements, "How many extra stamps to India," this would be useful both for photographers in India and advertisers at home.—I am, yours, &c., J. P. S.

India.

COPYING OIL PAINTINGS.

To the Editor.

SIR.—Pressure of work prevents me from replying this week to Mr. Dunmore and the unfounded remarks of "Free Lance," but I shall write in time for the next number of the JOURNAL.—I am, yours, &c.,

PICTON.

Answers to Correspondents.

* Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

REDUC.—It is the ordinary commercial neutral oxalate of potash that is used in the platinum process.

A. B.—There is no necessity to test the bromide of potassium if you purchase it from a respectable house.

G. H. S.—By $f/6$ or $f/8$ is meant that the working aperture or diaphragm of the lens is equal to so many times the focus of the lens. For example, $f/8$ means that it is worked with an aperture equalling one-eighth of the focus of the lens.

ALPHA.—There are several treatises on the manufacture of glass, any of which can be obtained through your local bookseller. Failing this, valuable information can be obtained, under the heading "Glass," in nearly all the better-class cyclopaedias.

B. O. B.—Lantern slides sent to exhibitions for competition are supposed to be the work, negative and transparency, of the exhibitor; but we do not think that any special objection would be made as to the originality of the negative. A slide taken from an engraving would not be likely to be accepted in competition.

C. A. WILSON complains that some emulsion he has made is very much slower than that with which commercial plates are prepared. He sends a couple of negatives which show a very good quality.—The fault appears to be due to insufficient cooking. A longer boiling will render the emulsion more sensitive.

W. CHATTON says he has seen permanganate of potash recommended for intensifying transparencies made by the carbon process, and asks the proper strength of solution to use. The strength is immaterial. The stronger it is the quicker, of course, is its action. About ten grains to an ounce of water is a good proportion.

OLD COLLEGE WORKER.—1. All the makers you name are good and you cannot go wrong with any of them. For negatives of lantern size select a lens not exceeding six inches in diameter.—2. If memory serves aright, the illustration is by the carbon process.—3. We have heard no more of Dr. Noire's new process.

ti. R. D.—To loosen the stopper, try the effect of applying a drop of paraffin oil at the junction of the stopper and the neck of the bottle and tapping with a hard bit of wood, then in a large piece of wood cut a hole sufficient to take to the top of the stopper, and give it a good wrench, the bottle being wrapped in cloth to prevent its cutting the hand in case of fracture.

T. R. ALLANSON writes: "I have just completed a new studio, thirty-four feet by twenty feet, full north light; would you kindly give me your opinion what colour would be the most suitable for the walls?—Any colour that is not too dark and is quiet will answer. A French grey or a light warm brown will do very well. What is to be avoided is any tint that will be trying to the eyes of the sitters."

D. R. C. says he has "invented an entirely new kind of instantaneous shutter which is much better than anything in the market," and asks if he can register it at Stationers' Hall in the same manner that photographs are made copyright.—An invention is not a subject for registration; it must be patented if you wish to secure a monopoly in its manufacture. A patent for four years will cost £4, or you can obtain protection for your invention for one year for 14.

G. R. writes as follows: "Messrs. — have taken a number of views of the scenery in our neighbourhood as well as most of the public buildings, and have made them copyright. These are now being sold by many of the stationers in the town. Is this fair, as it blocks the way from any one else taking the views?—Our correspondent is under a misapprehension; there is nothing to prevent him or any other person from taking similar views, and from exactly the same standpoint, if desired. The copyright is in the photographs and not in the subjects themselves."

J. P. S. (Bombay) writes: "A small (e.g. quarter-plate) negative is said to be, from its sharpness and other considerations, very useful for giving excellent and good-sized pictures by enlargement, instead of taking large direct pictures. Can an equally sharp and good negative be obtained with a full-plate (rapid rectilinear) lens and camera by using a quarter-plate carrier, and if so what arrangement of stop is best?—In reply: A full-plate lens will be quite as effective as a smaller one for use under the circumstances described. If the lens is good no stop will be required for the production of a very sharp quarter-plate negative."

A. STANESON asks if there is any better method of making the roof of a studio watertight than by putty and paint. He says his studio has been built many years, and, do what he will, it is always leaky.—There is no better plan than by the materials mentioned, if they are properly applied. Probably, as the studio is an old one, the putty has perished. In this case all the old putty should be clipped out and fresh applied. Many leaky roofs are caused by the instability of the sash bars, which yield by the force of the wind, and so cause the putty to crack away from the glass. The remedy in this case is to fit a stout iron bar transversely under the centre of the sash bars so as to give them greater rigidity.

LET requires: "Can the oxyhydrogen limelight be used for taking portraits at night? If so: 1. Is it necessary or desirable to use a screen between it and the sitter to diffuse the light?—2. Would there be any advantage in employing a condenser, such as is used in theatres?—3. Under ordinary circumstances what would be about the exposure necessary with rapid rectilinear lens, open aperture? Summarising these queries, we reply: No doubt the limelight can be employed for portraiture, but it must be screened by a large sheet or sheets of tissue paper. Both condensers and reflectors should be employed to throw all the light upon the screen, which will then enact the part of a luminous cloud that will light the face and figure with softness. One trial will determine the exposure requisite."

J. P. says: "I have a very fine single achromatic lens (meniscus, by Grubb). When using it for enlarging or reduction in the camera should the concave or convex side be toward the negative to be enlarged or reduced? If the concave, then of course it will be fixed in the copying camera in its normal condition, I presume; but if the convex side should be next the negative, how should the stops be placed? Should they be between the lens and the negative or between the lens and the sensitive surface? If the latter, is it sufficient merely to screw the lens into the camera from within, without changing it in its mount at all, the lens being flush with the outside of the camera front and the tube with the stops inside the camera?"—In reply: Here is a simple rule by which this matter will be readily understood. When the lens is employed for enlarging from a negative then must the convex surface be next to the negative, but if a reduced copy of the negative is required then must the convex surface be next to the sensitive surface. The stop must always be next to and at some distance from the concave surface of the lens.

NOVICE writes: "I have recently been using —'s instantaneous plates and —'s rapid shutter, but all the negatives yield prints like the enclosed—all black without any detail or half tone: why is this?"—The reason is that the negatives are very much under exposed. It is next to useless to attempt instantaneous views of London street scenes in such light as we have had lately. You must not imagine that by the use of the so-called "instantaneous plates" and extra rapid shutters you will be enabled to obtain good negatives under every condition of light.

PHOTOGRAPHIC CLUB.—January 23, 1889.—Subject, *Development*. On January 23 all lantern slides intended to be shown at the special lantern evening, on January 30, must be sent in.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Monthly technical meeting, January 22, 1889, at the Gallery, 5A, Pall Mall East, at eight p.m. Subject *Effect of the Green Band of the Spectrum on Bromide and Chloride Plates*, by Mr. Friese Greene.

MR. WILLIAM TYLAN sends us a slide protector for packing slides when on cycling excursions. He says he has had them in use for some time. This is *à propos* of our article on the subject on pp. 18 and 19 last week. It is a nicely made case with a flap at each end.

DINNER OF THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Mr. England writes us that "it is decided to have the Photographic Society's dinner at the Café Royal, and on the same evening as the Solar Club, and unite the two. Therefore the dinner will take place on the second Monday in February. Tickets can be obtained by writing to me."

ARTISTS AND THE PARIS EXHIBITION.—The *Daily News* correspondent telegraphs:—"English artists will be glad to hear of an announcement which was made to-day by the Minister of Public Instruction. It relates to the exhibition of pictures in the International Exhibition. Artists who intend to compete for admission will, it says, be granted an extension of time for sending in their works to the committee—namely, to the 15th February."

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION FIXTURES.—January 21, *On Making Backgrounds* (practical): Mons. M. Tuquet. February 4, Lantern exhibition—*A Visit to the Land of the Midnight Sun*: Professor Clowes, D.Sc. February 11, Smoking concert. February 18, *Photo-Micrography*: Messrs. W. N. Pratt, F.R.M.S., and F. W. Cave, F.R.M.S. March 4, *Experiments in Printing Processes*: Mr. W. J. Collings. March 18, *Magic of Science; a Night's Amusement with Photographic Chemistry*: Mr. J. C. Lancaster. March 25, Smoking concert.

THE PARIS INTERNATIONAL EXHIBITION.—In the interests of several intending exhibitors who desire to know details concerning this exhibition, we have applied to Mr. Trueman Wood for information. Mr. Wood says:—"The exhibitors of photographs are on the same footing as all other exhibitors, i.e., they have to pay 5s. per square foot of floor occupied if they have stands or show-cases, 2s. 6d. a square foot on wall or screen. All the space has been for some time disposed of. I was hoping—and have not yet given up all hope—that I might get a free space for an exhibition of amateur photographs. If anything of the sort is done you shall know."

ANNUAL DINNERS.—A party of over eighty, being the *employés* of Messrs. Watson & Sons, High Holborn, together with a few guests, dined together at the Holborn Restaurant on Saturday last. Mr. T. P. Watson, the head of the firm, presided. After the usual loyal toasts, Mr. Watson paid a tribute to the various heads of departments and also to the men, by whose excellence of management and workmanship the firm had been able to attain the high position it occupied, one evidence of which was the great number of medals received by them in competitive exhibitions both in this country and abroad. The meeting was of the most harmonious character, many toasts, speeches, recitations, and songs, being given.

The annual dinner of the North London Photographic Society took place on Tuesday last in Myddelton Hall, there being a good attendance. Mr. J. Traill Taylor presided, Mr. E. Clifton being Vice-chairman. Mr. E. Dunmore in responding to one of the toasts, that of "The Photographic Club," observed that when the original North London Association of twenty-five years ago broke up, many of its members allied themselves with the South London Society, and when it in turn ceased to exist its members joined the Club. The proceedings terminated, as usual, by the singing of "Annd Lang Syne," shortly before midnight.

No. 1499. VOL. XXXVI.—JANUARY 25, 1889.

DEFECTS IN SENSITISED PAPER.

In returning to this subject, partially discussed by us a fortnight ago, we are impelled at the outset to take up one particular phase of the topic through a cause of complaint having come before us which clearly showed the existence of a want of knowledge in this direction. The primary complaint was that a certain series of negatives must have been badly executed, as prints recently made from them had not the brilliancy and sparkle of those produced a couple of years ago from the same set of negatives. *A priori*, there was here a strong case against the negatives until the results came to be investigated, when a little knowledge put a different complexion upon the matter. The whole cause lay in a different sample of albumenised paper from that used for the first batch having been employed in the recent prints. It is a fact not sufficiently known that at the present time albumenised papers can be obtained of far more varying characteristics than was once the case. Thus, we have in our possession as we write two samples of paper, equally glossy to the eye, yet one of which will, with a rather weak negative, give a rich and crisp print, while with the other nothing but flat, poor prints can be obtained, although with what might be termed a negative of average density prints of great excellence can be produced. Here, then, it is evident that a photographer working with the first kind for a length of time, and producing a class of negative that suited it, would at once say his paper was defective if he used some of the second kind. It will perhaps be sufficient if we thus draw attention to a quality capable of influencing results to such an extent as to lead to a paper being put aside as defective, though capable of producing the highest results. Whether one or the other of the two kinds is the better we will not now stay to inquire.

There is, however, to the variety of qualities possessed by albumenised papers a parallel in the variety of tones desired; and so marked is this, that a considerable amount of photographic instruction as regards printing will have to be rewritten. The old text-books all stated that a silver bath for albumenised paper ought to be kept acid; but after a time the practice of large printers showed that with an acid silver bath "purple" tones, which at one time were entirely in demand, were with difficulty obtained, and it was then pointed out that the silver printing bath must be neutral, or defective prints would be produced. It does not need to be pointed out to any one accustomed to examining the results of our leading photographers, or to frequenting photographic exhibitions, that some of the very finest work of the day is printed in tones the

very opposite of purple, tones of such sort that to obtain them a bath acidified with citric acid would be most suitable. The use of the burnisher, which increases the warmth of tone while adding to the transparency of the shadows, may have had something to do in working this revolution; for such is undoubtedly a correct term to use in this connexion. Whatever the cause may be, the fact remains that when sensitised paper which would once have been looked upon as perfect is tried for obtaining these rich, ruddy brown tones, it would be at once pronounced defective.

Paper is now prepared of such high gloss that other so-called defects show themselves, and have, to our knowledge, led to some samples being returned which really were of the very highest quality. Chief among these "defects" may be cited the presence of innumerable fine fissures in the surface of the finished print after mounting. The cause of this is, or ought to be, obvious, and is analogous to what occurs when an enamelled card is bent sharply. The enamel breaks, mainly in one or two deep cracks; in these defective albumenised paper prints the enamel, i.e., the coagulated albumen, breaks, but into a large number of cracks. The conditions governing that breaking are, first, that the surface of the print be perfectly dry, and, secondly, that the print has dried with a curl. The remedy is obvious; the wet prints must be treated so as to dry perfectly flat, or, which is better, they must be mounted before they have been once allowed to dry. If cracks show in the latter case the paper may be not unfairly pronounced defective.

The high gloss brings another defect in its train in the drying of the silver bath in "tears" upon its surface, and so causing patches of uneven colour on the finished print. There are several remedies for this defect, the chief of which is, perhaps, the reducing the strength of the silver bath so that the coagulation is not so instant and complete, partially drying the surface of the sheet, after it is drawn from the bath, by pressing dry blotting paper upon it, and, finally, always drawing the paper over a glass rod before pinning up to dry—a plan used by all large users of paper, but not sufficiently attended to by those who use smaller quantities. Possibly the difficulty and "bother" of fitting up the rod deters the latter; but this need be no obstacle, for if the edge of the dish which holds the solution be clean, and be not chipped or otherwise irregular, the same effect almost may be obtained by drawing the paper, as it leaves the bath, in such a manner that it catches this edge, where, till the whole sheet is removed, it will adhere during withdrawal, and most of the fluid upon its surface be scraped off as it were.

We will conclude our list of defects by an account of a series of them, derived from a professional photographer in a large way of business, but which might be equally applicable to the veriest tyro. In this instance the finished prints bore a variety of stains and marks, irregular in shape and in distribution, which caused a considerable amount of anxiety. It was, however, quickly decided that they were more like "hypo" stains than anything; but the puzzle was, How did they get there? Daily were the toning operations watched to discover whether any carelessness of handling took place when washing the prints before toning, but nothing of the sort could be seen.

After fruitless efforts at discovery, the cause was at last found out. The printer who was usually detached for fixing the prints was not very careful as to how his clothes touched the bench whereon the fixing trays were located, and it was proved that the defects were distinctly traceable to prints and paper which had in the earlier stages passed through his hands. To insist for the future that his printers must always wear a high apron during fixing operations led to complete future immunity from these defects, the accident proving once more the necessity of the utmost cleanliness in every operation in photography, from the most important to the most insignificant.

THE LATE J. R. SAWYER.

AN earnest worker and clear-headed man has been removed from amongst us. Mr. John Rober Sawyer died at Naples, on Monday, the 21st instant, in the sixty-first year of his age.

Mr. Sawyer had for a great number of years been inseparably associated with the Autotype Company, of which he was a partner, and of whose Works at Ealing he was Director. In that capacity he introduced many improvements in permanent photographic printing, and published much of a highly practical nature. The *Autotype Process*, of which we possess six editions, was an emanation from his brain and pen; *Autotype and Chromotype Notes and Queries*, which succeeded the manual just named, was edited by him; and more recently *The A B C Guide to Permanent Photography*, published in the summer of 1887, claims Mr. Sawyer as its author. His method of developing pigment pictures upon a flexible support is known and practised by every carbon printer, while his system of photogravure is quite fresh in all our memories.

For some time Mr. Sawyer's health had been bad, but it was only three weeks ago that he was compelled to give up work and try the effect of a residence in the more genial climate of Naples. We learn from his partner, Mr. W. S. Bird, that on the 18th instant he was in a fairly cheerful frame of mind, on which date he wrote him a note, but his symptoms became rapidly worse, and the heart refused to continue action. His eldest son at once started for Italy, but arrived too late to do more than pay the last duties to the dead.

An "advanced" man in all that pertains to social life, Mr. Sawyer was a supporter of the Cremation Society, and desired that his body should after death be resolved into its elements by fire, which it was decided should be carried into effect at Milan, which possesses the most perfect crematorium in Europe.

Mr. H. H. SCULLER recently described before the Philadelphia Photographic Society what may be truly termed the largest camera in the world—the Lick telescope—as arranged for photographic work. As we have described, at intervals, the progress of the great instrument as it approached completion, it will not now need details to be given to enable our readers to understand the main points of construction. It will be remembered that an extra disc of glass survived in the process of manufacture, and was purchased for the purpose of being ground to such curves as would enable it to form a photographic auxiliary, and that it is now in use. When applied to the ordinary objective as a corrector for photography, the "camera" has to be

shortened ten feet, or, in other words, the focus is diminished to that extent, and thus permits the dark slide for 20 x 20 plates to be placed *in situ* in front of the eyepiece without disturbing it; and all starry objects coming to the same focus in one instrument, there is no need to perform the operation of focussing. Large as are the images produced by an instrument of such long focus it is yet desirable at times to amplify them and to carry the operation out; the enlargement is made at one operation with this instrument by placing a lens of two inches diameter and twelve in focus in the place of the dark slide. This considerably increases the size of the image, which is received in a small camera placed nearer the eyepiece. It is only comparatively recently that this great camera has been put to work, but already its first fruits have reached this country in the form of photographs of the moon superior to anything hitherto achieved.

At the Annual Meeting of the Royal Meteorological Society, last week, the President (Dr. W. Marcey) gave an address on fog, a subject always of interest to photographers from more points than one. However, it was "London fog" that was specially alluded to on this occasion. Adopting Professor Tyndall's theory, that each particle of condensed vapour is coated with coal smoke, Dr. Marcey explained that it was a well-known fact in meteorology that cold air on the summit of hills, being heavier than that below, slid down the slopes, so that the lower portions of the hillsides were really colder than the plains beyond. London is surrounded with hills, and on them the air was colder than in the town, with its burning gas, coal fires, and furnaces. He then pointed out the difference between London fog and the fog or cloud on a mountain top. In the case of the former, carbonic acid, he said, was abundantly found in the fog itself, chiefly from coal smoke; while fog or clouds on mountains were far away from this source of contamination. The address was a most interesting one to photographers.

SPEAKING of London fogs. It may be mentioned that they are frequently very local and sometimes very shallow, even where they are the densest. A London fog may be very thick indeed a few feet from the ground, while the atmosphere but a little distance above may be perfectly clear and bright. It is no unusual circumstance, for example, for one of those dense, smoky fogs, for which the metropolis is so renowned, to prevail in, say, St. Paul's Churchyard, while at the summit of the Cathedral, or even only halfway up, a cloudless sky may be seen, with the sun shining brilliantly on the fog below. It is a curious sight, and one worth the ascent to witness.

In the County Council Elections portraits of many of the candidates have figured conspicuously on their advertisements. The majority of the blocks from which they were printed have been produced photographically, not direct however, but from sketches made from photographs. These are copied in the camera, and from the negatives thus obtained typographic blocks are made in the ordinary manner. The majority of the portraits are very poor productions, being about on a par with many of those which are issued by the police authorities of persons "wanted." At the next general parliamentary election we strongly suspect that photographic processes will be more extensively utilised than on any former occasion. In several past elections it has been customary with some candidates to circulate their portraits, almost broadcast, amongst the constituency as a means of enhancing their popularity. The portraits issued on these occasions have, for the most part, been very different productions from the majority of those alluded to on the addresses of the aspirants for the new body. In most instances either collotypes, Woodburytypes, or, in some cases, silver prints have been circulated.

It is much to be regretted that those who have employed photography to illustrate subjects of lasting interest, have not had the examples printed by some one or other of the permanent processes. Or, if this were not done in the first instance, had the pictures reproduced by some method by which they would be lasting. We recently saw some illustrations to a pathological work which had been printed in silver some few years ago, many of which had faded so badly as to be

now of no value for the purpose intended. As some of the cases illustrated were said to be unique, it follows that the fugitiveness of the prints may prove a serious loss to the medical profession at some future period. The photographs in many scientific works which are fading would amply repay for reproduction in any of the processes by which they would be permanent—provided, of course, that the work be taken in hand before the fading has gone too far.

A short time back we pointed out how some charming effects in the lantern might be obtained with frost and snow pictures—or, indeed, with many others—by covering them with tinted glasses. A difficulty may often be experienced in small towns in obtaining glass of the desired tint and of the right density. This may be overcome by taking advantage of some of the coal-tar colours. They are very transparent, and many of them are freely soluble in alcohol. If a little of the dye be dissolved in collodion or negative varnish, and then be applied to plain glass, it will answer quite as well as coloured glass itself. By this means any tint may be obtained, which is not always the case with tinted glass; and by increasing or diminishing the proportion of the dye the density may be varied at will.

SATURATED SOLUTIONS.

AMATEURS who compound their chemicals from saturated solutions too frequently overlook an important factor in the case, namely, temperature—taking it for granted that “saturated” means a definite quantity. It is scarcely necessary to point out, to the majority of our readers, that this is a fallacy. A saturated solution at a temperature of, say, 65° is often of a widely different strength to what it would be at, say, 55°. Notably is this the case with some of the substances employed in photography—alum, or the sulphate of iron, for example. If a saturated solution of the latter salt be made with water at 65°, and then be subjected to a reduced temperature, such as we had a week or so back, a considerable quantity of the sulphate will crystallise out, and so render the solution weaker. The same will happen, though to a less extent, with oxalate of potash.

Now it is easy to see, if a ferrous-oxalate developer be made with such solutions, that it will not have the same developing energy as one containing the normal quantity of the salts. Hence, many inexperienced workers are led, from seeing the image abnormally long in making its appearance, to suspect under exposure. We know this matter has been a source of trouble, of late, with two or three amateurs in enlarging on bromide paper, and probably has been with many others. Although the pictures were fully exposed, the slow appearance of the image, which was rendered still slower by the coldness of the developer, they were assumed to be under exposed, and this ended in many failures, and, in one case, to a condemnation of the paper itself. It was assumed that sheets of different sensitiveness had been put up in the same packet, because similar results to those secured some little time previously, with the same negative and exposure, could not be obtained; whereas the trouble really arose from the much weaker developer employed to bring out the image. The discrepancy in colour often met with at this season of the year may sometimes be traced to the same cause. The solubility of alum is still more influenced by temperature than is the sulphate of iron. Clearing solutions are usually made with a “saturated” solution of alum mixed with an acid. It may be mentioned that in some instances, when so compounded, the solution may contain as much as double the amount of alum that it does in others.

ECHOES.

So many are the different forms of “flash lamps” now in the market, and so popular has become the use of magnesium by their means for portraiture, that it is difficult to believe it is little more than twelve months since the subject of the “flash light” was brought before the Glasgow Photographic Society for the first time in this kingdom by Mr. T. N. Armstrong, yet such is the case. Yet, as remarked by that gentleman in his more recent communication to the same Society,

published last week, very little effort has been made to systematise this application of artificial lighting so as to render it commercially useful for portrait purposes; and I quite agree with him also in his opinion that some of the contrivances introduced are little better than “ridiculous toys.”

His efforts therefore, in conjunction with a fellow member of the Glasgow Society, to reduce the employment of the flash light to something more of a certainty, even if they do not end in attaining “unerring precision,” must be characterised as praiseworthy, and deserving of the thanks of the profession. But it is unfortunate that in the brief printed report of the meeting at which his paper was read, although accompanied by the full text of the latter, it is impossible to convey to the outside reader the same full information on the subject that was, I have no doubt, given to those present. Reading for myself, I must confess that I but imperfectly comprehend the details of the lamp described, which is perhaps not to be expected without an actual inspection of the affair, and that in one respect, at least, it seems to me not to invite general adoption except in large establishments, where considerable recourse is intended to be had to that form of light, if even there.

The employment of the limelight as an auxiliary, however efficient it may prove in actual use, will scarcely be hailed as a simplification; on the contrary it will, I venture to say, be voted a complication by the vast majority of the readers of the JOURNAL. The working of the limelight, I am fully aware, has been very greatly improved and simplified of late years, but especially by the introduction at a cheap rate and in convenient form of the condensed gases; and, thanks to the present popularity of the lantern, its principles are now more perfectly understood, and almost every one is now more or less familiar, theoretically at least, with the rules to be observed in order to secure safety. Yet I am convinced that it is yet only the comparative few who are, *practically*, sufficiently well acquainted with its use, and so placed with regard to obtaining a convenient supply of gas, to look upon its introduction into the studio as an unmixed benefit.

Those few regular users of the limelight who have by constant practice attained a perfect familiarity with its working are too prone, encouraged by a fortunate immunity from accident, to express a confidence in it that almost amounts to contempt for its dangers in less competent or careful hands. I know more than one such practised “hand” who metaphorically smiles at the suggestion of danger when he himself is working, but who is particularly careful to prevent any one else from interfering with his arrangements, and very chary of accepting outside assistance of any sort, thus acknowledging that the safety presupposes the possession of an amount of intelligence and carefulness that he does not credit to ordinary mortals. But when Mr. Armstrong says he considers “there is far more danger to be apprehended from a common oil lamp than from a limelight jet at any time,” he seems to me to be going further than most limelight operators, and will scarcely, I fancy, carry general opinion with him.

That the oxyhydrogen light may be beneficially introduced into the studio without any great cost or inconvenience in some of our large cities I do not doubt, but, as I have suggested, the use that is made of it will have to be considerable in order to make it worth while. In out-of-the-way places the trouble and expense of renewing the gas supply—I do not refer to the cost of the gas, but the carriage and time wasted—will prevent many, even large workers, from adopting it; while in short-handed establishments the extra work involved is scarcely calculated to promote safety.

In another column last week I find a description of a new lamp “to be used for photographing by magnesium light,” for which a patent has been obtained. I will not describe it as a “ridiculous toy,” but, as far as I can see from the specification, it presents some points which, on the surface, have not a very practical look. For instance, the bottom of the lamp consists of “a thick piece of ground glass,” and the magnesium powder, mixed with chlorate of potash gunpowder, or any other combustible, is for use “laid in a train on the upper surface of the ground glass bottom,” and “the duration of the exposure is regulated by the length of the train.” Now, I should like to ask, What is likely to be the average “life” of a lamp with a ground glass bottom over which a serpentine stream of intense combustion is constantly—so long at least as it lasts—meandering?

Not long I imagine. I remember once exhibiting the gun-cotton flash light to a small audience, employing an earthenware plate upon which to make the flash, and the unanimous opinion expressed was that it would prove a rather expensive light "if you have to use a fresh plate every time," for the plate succumbed to the heat; and if earthenware, how much more "thick ground glass," especially when the heat "drags its slow length along" a narrow path. If it were a new method of dividing glass by means of heat it would be comprehensible.

Then, again, the duration of the exposure depends upon the length of the train, so no doubt it will do; but how is that length to be calculated, or rather how is a uniform duration of exposure to be assured with a given number of inches of train? I opine that the quantity of material will operate materially in affecting the duration of combustion, to say nothing of the intensity of illumination, and I am inclined to think that any "system" of exposure based upon such frail data would prove misleading in the extreme.

One other matter strikes me, namely, the mention of gunpowder. If by "gunpowder" is meant the "villainous mixture of saltpetre," it is well for the sake of the atmosphere of the studio and the olfactory nerves of the sitter that the lamp is intended to be "smoke tight." But what about cleaning the lamp and the actinic value of the light, even if that operation is most carefully performed after each exposure? The white fumes of oxide of magnesium would not matter so much, though even they arrest some light, but I do not imagine the cloud of imperfectly consumed carbon could be thus lightly regarded; and setting quite on one side the "fouling" propensities of ordinary gunpowder, it seems to me that a very great deal of magnesium would be burnt to waste. It is possible, however, that "smokeless" powder is meant; if so, why not state so explicitly, even though it be in the specification of a patent?

I thought I had finished, but find I must refer to yet another point. It is claimed that the lamp "can be suspended in such a manner that the light falls on the sitter from the same directions as in daylight portraiture." We are told further on that the area of the front surface should not be made smaller than twenty-one inches by twelve, so that presumably those are the approximate dimensions of the "skylight," whose effects it is intended to imitate. Truly, "taking one consideration with another," this must be a fearfully and wonderfully made piece of apparatus if it answers its inventor's aspirations.

In his paper on *Collodio-Bromide Emulsion*, read before the Society of Amateur Photographers of New York, Mr. F. C. Beach alludes to the difficulty arising in contact printing upon sensitive collodion films from their extreme tenderness, and the consequent liability to damage from pressure or friction against the negative. This is no merely imaginary trouble; indeed, I think sufficient stress is scarcely laid upon it either by Mr. Beach or previous writers. Actual friction is not necessary, for the mere pressure—and that in a very moderate degree—suffices to produce innumerable minute pinholes or perforations in extremely delicate films unprotected by any gummy or varnish-like preservative, such as those prepared from a "washed" emulsion. In the case of unwashed emulsions, where a preservative is employed, the dried film generally possesses greater hardness or resisting power, either produced by the direct indurating effect of the substance employed upon the collodion, or more commonly arising from the fact that its pores are filled and its surface covered with a comparatively tough substance that partially protects it from slight injury. But even then the greatest care is needful to avoid rubbing the two surfaces together, however gently.

It has been suggested to interpose a mask of thin paper between the negative and plate, so as to separate the two surfaces to an infinitesimal degree, and this, under proper precaution, proves an effective remedy even in the case of lantern slides, though no doubt many operators would look askance at any such suggestion as tending to degrade the sharpness of the resulting image. I do not think there is much real cause for alarm, but in lieu of that method I would suggest the employment of specially constructed frames instead of the ordinary printing frame usually employed, one such being now, I believe, in the market. This should be more of the character of the single dark slide, with a backboard hinged to the frame instead of being detached, as in the case of the printing frame for paper

proofs, from which the transparency frame differs in not requiring a decided backboard to permit of the progress of printing being examined. The attachment of the backboard to the frame gets rid of one chief cause of rubbing the films together, as contact is made by a direct downward pressure without any chance of side movement in fastening the springs. If the negative and plate be made to drop into a rebated cell of the exact size, the risk of shifting is altogether removed, or if the negative be larger than the plate a mat of card-board, with an opening the dimensions of the plate, can be inserted to hold the latter safely in position, and the danger is then reduced to that arising from simple pressure. This may be removed or reduced to a minimum by a proper arrangement of springs, which, as in the dark slide, will be fixed to the inner side of the hinged back. The extremities of a single bow spring, such as ordinarily employed in the dark slide, by bearing upon two points removed from the centre of the plate, will, by spreading the pressure, lessen the risk of bending the glass and causing it to bear too heavily on the negative. But if four separate little springs bearing upon the corners or edges of the plate—or, what is perhaps simpler, two bow springs attached by the same screw to the centre of the back and crossed at right angles—be employed, the pressure will be applied at the least dangerous points, and even in the case of uneven glass will scarcely exert any injurious influence on the material portions of the plate. There is much room for improvement in the appliances for transparency contact printing.

There is a somewhat remarkable description in last week's French correspondence of a vignetting mask exhibited before the French Society. It is described as a zinc plate perforated in the centre, and is intended to "render great service in producing photographic busts," whatever they may be. But the noticeable fact is that "the oval hole is at the same time pressed upwards by means of a die." The bodily lifting of the "hole" from the sheet of zinc is a novel mechanical feat, and reminds one of the Hibernian's description of how to make a cannon by "taking a long hole and pouring brass round it."

A novel lens exhibited at the same meeting is also fully entitled to the description of remarkable. It is intended, we are informed, "to take part in the forthcoming struggle for fame, as it is entered in the competition for optics;" but what most concerns me is that instead of being of transparent crown and flint, like ordinary lenses, it is "cut" (*sic*) "out of blue and yellow glass." This is indeed an innovation, for if the colours are only pronounced enough we have both the visual and chemical rays cut off to the not very manifest advantage of either ease in focussing or rapidity of exposure. The idea was received as "good and novel." The latter I can quite believe, but we have to wait for time to show whether or not it is of use in practice.

And—oh, fie!—the members being "under the influence of the holidays," very little business was done. JUNIUS.

FURTHER PROGRESS IN SPECTROSCOPIC PHOTOGRAPHY.

IN the month of June of last year I wrote a short paper on the solar photographic spectrum of Mr. George Higgs, of Liverpool, as I had just had the pleasure of comparing it with Professor Rowland's grand spectrum in the library of the Royal Astronomical Society, and I could not help expressing my surprise and delight at the perfection of the results obtained at Liverpool. This first spectrum of Mr. Higgs extended only from W.L. 3860.8 to 4404.3, including the regions around G, h, and H, but he has since continued his labours, and the negatives now embrace the whole spectrum, from the extreme violet to a point considerably beyond D, with the exception of a certain portion near F. The print from the negative, which extends from W.L. 5080.0 to 6064.5, including b, E, and D, is less distinct than the more refrangible portion of the spectrum, as might well be expected from the extra difficulties that necessarily present themselves as we approach the red end of the spectrum. But it is not my intention to dwell, at present, either on the value of the negatives or on the nature of the prints taken directly from the negatives, but I wish to draw special attention to the enlargements from these

negatives, three of which I have had the privilege of examining and comparing with other photographs and drawings. The most striking feature of these enlargements, at first sight, is the extreme clearness with which every line stands out on the bright background, nothing hazy or obscure, the whole a perfect marvel of distinctness and sharpness of definition. All must admire the fine solar spectrum made with an interference grating by Professor L. M. Rutherford; and yet viewing this grand work, and then turning to the enlargements of Mr. Higgs, is like looking at the delicate outlines of a fine public edifice first through a November fog, and then in the brilliant sunshine of a clear spring morning. It must be borne well in mind that I am now referring, not to the original negatives, but to the enlargements on about the same scale made, one by Mr. Oscar G. Mason, and the other by Mr. Higgs, using an original method of his own. Before I saw the pictures of Mr. Higgs I was struck with the beauty of Mr. Mason's print, and although I still admire the latter, I now know that it is possible to possess something much more perfect. If attention be paid solely to the stronger lines the difference is less apparent, but when we turn to the fainter markings, there can be little doubt that the above illustration is no exaggeration.

Many of my readers will probably have examined the three exhaustive drawings of the visible spectrum, made in 1884, at Winchester, by Professor Huxley Smyth, with a fine Rowland grating 85 by 50, the surface being ruled at the rate of 14,438 lines to the inch. A tabular comparison of the results obtained by Mr. Higgs with the eye observations of Angström and Smyth, and the photographs of Rutherford and Vogel, will give the most satisfactory idea of the success of the work. I will take, for instance, the fine lines on the less refrangible side of the G group.

Angström.	Huxley Smyth.			Rutherford.	Vogel.	Higgs.
	I. Winchester.	II. Winchester.	III. Winchester.			
W.L. 4313.6	Double 0	Double 0	Double 0	Single 0	Double 1 Faint line	Double 1 Faint line
4314.5	Double	Double	Treble	Fainter on one side	Double	Double
	1 Faint line	3	2	1	2	3
4316.4	Do.	Do.	Do.	Do.	Do.	Do.
	3 Faint lines	3	4	2	5	5
4318.0	Do.	Do.	Do.	Do.	Do.	Do.
	3 Faint lines	1	4	1	3	5
4320.1	Do.	Do.	Do.	Do.	Do.	Do.

The only instance in which a line appears in any of the above spectra, and there is not a corresponding one in the print of Mr. Higgs, is at 4314.5, but here the treble line with two lines following in the III. Winchester are probably identical with the double line and the three following lines of Higgs.

I should mention that the photographs of Rutherford and Higgs have been examined without the assistance of any lens. Probably the exquisite definition of the enlargements of Mr. Higgs would render the comparison still more striking if optical power was used in the examination.

This wonderful distinctness in the enlargements, which makes the prints almost, if not quite, as valuable as the original negatives, is due in great measure to the method adopted by Mr. Higgs for getting rid of the granular structure of the metallic silver in the process of copying. The method, which is probably original, or at least suggested itself independently to Mr. Higgs, consists in a mechanical movement of the plate parallel to the lines, or in the use of a cylindrical lens, convex if placed in front of the enlarging lens, or concave if behind it. The results obtained by this new method are a great advance on anything I have as yet had the pleasure of examining, and I feel sure that many who are engaged in similar researches will be very grateful to Mr. Higgs for generously making known a discovery which in his hands has already proved so eminently successful. The negatives are prismatic pictures, but, as diffraction spectra are likely to possess a much greater scientific value, Mr. Higgs is now preparing to repeat his work with a large Rowland grating. When the diffraction negatives are completed, and a fresh series of enlargements produced by the newly invented

method, we shall then be supplied with a solar spectrum as perfect as the dispersive power of the instrument employed is capable of producing.

S. J. PERRY.

A SIMPLE FORMULA FOR FINDING THE EFFECTIVE APERTURE OF A RECTILINEAR, EURYSCOPE, PORTRAIT COMBINATION, OR THE LIKE.

Is a photographic lens, where the diaphragm is placed between the lenses, the usual method of finding the ratio of focus to aperture, by dividing the equivalent focus of the combination by the actual diameter of the diaphragm, gives only an approximate result, for this reason, that the actual aperture of the diaphragm is not always the effective aperture of the combination. As the speed of the lens depends on this ratio, it is important that the effective or true working aperture of the combination should be known.

The exact relation of focus to aperture for parallel rays is expressed by the formula—

$$\frac{pa}{p-d} = \frac{f}{n}, \text{ where,}$$

p = principal focus of front lens or combination of lenses in front of the diaphragm.

a = diameter of aperture in diaphragm.

d = distance between front lens and diaphragm.

f = equivalent focus of the entire lens.

A = effective or working aperture of the entire lens.

$$n = \frac{f}{A}$$

$$\text{Then } n = \frac{f(p-d)}{pa}, \text{ and } a = \frac{f(p-d)}{pn}.$$

EXAMPLE I.

$$p = 0.4, a = .005, d = \frac{1}{2}, f = 5\frac{1}{2}, n = \frac{5\frac{1}{2} (0.4 - \frac{1}{2})}{0.4 \times .005} = \frac{51.75}{9.1675} = 5.645.$$

This lens is therefore working at $\frac{5.75}{5.645}$, or a shade less than U.S. 2.

By ordinary method, $\frac{5.75}{.005} = 5.00$, which is .315 too great.

EXAMPLE II.

With the same lens a stop is required to give it a working aperture of U.S. 16, or $\frac{f}{16}$.

$$\text{Then } n = 16, a = \frac{5\frac{1}{2} (0.4 - \frac{1}{2})}{0.4 \times 16} = \frac{51.75}{152} = .34.$$

By ordinary method $\frac{5\frac{1}{2}}{16} = .340$, which is .019 too great.

EDWARD M. NELSON.

"PLATINO-URANOTYPE" AND "MERCURO-URANOTYPE," TWO NEW URANIUM PRINTING PROCESSES.

[A Communication made to the Sheffield Photographic Society.]

THE two methods of obtaining positive prints, which I have the honour of presenting to your notice to-night, are, I believe, novel; and before I proceed with the subject of my paper, I beg to say a word or two of explanation.

Last winter (1887), when there was very little chance of obtaining shots with my camera, I amused myself by trying various processes of printing, amongst others the exceedingly old one of printing with salts of uranium.

As you all doubtless know, in this old process paper is simply coated with a strong solution of uranic nitrate, and is then dried. It is then placed behind a negative in the printing frame, and a faint image, full of detail, printed on it—direct sunlight being best for this purpose. This image is then developed by floating the print, face downwards, on one of the following baths:—

1. A weak solution of gold trichloride.
2. A solution of ferricyanide of potassium.
3. A silver bath.

The print is fixed by a rinse in a very dilute solution of hydrochloric acid, followed by a thorough wash in ordinary water. With the gold bath, a vigorous violet image due to metallic gold results; with the ferricyanide bath, an image of a burnt sienna colour is obtained; and lastly, with the silver bath, a grey image.

I was much struck with the softness of the images and the amount of detail given by these methods, but at once recognised the coarseness of the tones obtainable being the reason that the process was laid on one side as merely an interesting fact.

I tried a platinum bath as a substitute for those I have mentioned, with the natural result that no visible reduction of the latter took place. I thought no more concerning the subject until November last, when reading about the reactions involved in the various iron printing processes, I was struck by the remarkable analogy which exists in the behaviour of the ferrous and uranous salts with solutions of potassium, ferricyanide, and of salts of gold and silver. Not unnaturally I conceived the idea that this analogous behaviour might extend to the salts of platinum. Now the ferrous salts, such as ferrous oxalate, although they will reduce auric chloride to the metallic state, will not, without the assistance of a further reducing agent, such as neutral oxalate of potassium, reduce platinum from its salts. It was the discovery of this fact that enabled Mr. Willis to produce and patent his beautiful "Platinotype" process.

I presumed, then, that an assistant to the reducing power of uranous nitrate was all that was required to render possible a new process of platinotype on an entirely novel foundation. Starting on this basis, I tried sensitising paper with solutions of uranium nitrate and potassium platinous chloride. The paper was exposed behind a negative and a faint grey image printed by a few minutes' exposure to direct sunlight. This was then developed in a hot, slightly alkaline solution, composed of hydroquinone, formic acid, and ammonium carbonate. I obtained a slight reduction of platinum by these means. Further experiments showed me that printing should be stopped as soon as any trace of the image becomes visible. With prints given this much shorter exposure, I thought I had solved the problem, for prints thus treated developed with the greatest beauty; but after they were washed and dried I was disappointed to find that the image was grey and flat on the surface, having sunk into the paper, as was shown by the fact that on viewing the print as a transparency the image was full of vigour. This I attributed to the strong and hot developer attacking the sizing of the paper, and I am now convinced that such was the case. Now if into a test tube you pour some of this hot solution, and into this a few drops of platinum solution, an instant reduction of the latter takes place. From this it is easy to see that the reactions involved are not so much a question of the reducing power of uranous salts on those of platinum as one of uranic salts preventing or protecting the platinum salt from becoming reduced by an otherwise sufficiently powerful reducing agent, and that the action of light on the uranic salt, reducing the same to the uranous state, serves the purpose of removing a barrier to the action of this reducing agent or developer.

With this theory as a guide, the problem became much simplified, since a choice of developers becomes very easy by test tube trials. A cold solution in the first place obviously would be desirable, and the following seems to be suitable:—First make a saturated solution of neutral oxalate of potash, and dissolve dry ferrous oxalate in this to saturation. By the use of this cold development I got over my main difficulties, for I have, as you will see later, obtained platinum prints in half tones, and it is to prints thus obtained that I have given the name of "Platino-Uranotype."

It will be needless to call your attention to the fact that, like Artemus Ward's tale, "they are far from purflick," but they will serve the purpose of affording proof of my success so far as the rough chemical problem is concerned. The refinement and perfection of the process can only be achieved by repeated and patient trial, in order to ascertain the best proportions of the sensitising solutions, &c., and my object in bringing the matter before your notice at this very early stage is in the hope that far more competent hands than my own may be started in this direction. The process is very simple, for the operations involved are merely:—

1. Coating the paper.
2. Exposing same in printing frame.
3. Development (which takes only five to ten seconds).
4. Fixing in HCl (one and a half per cent. solution).
5. Rinsing in water, drying, and mounting.

In my most recent experiments I have substituted the uranium chloride for the nitrate in the sensitising solution, and I am inclined to think that better results are to be obtained from its use. As in Mr. Willis's processes, chlorate of potash may be added in minute quantities to the sensitising solution to increase contrasts.

As far as my necessarily limited knowledge at present goes, the following seems good proportions for the sensitising solutions:—

A.	
Saturated solution of uranium chloride.	
B.	
Potassic platinous chloride.....	60 grains.
Water, distilled	1½ ounce.

Ninety minims each of A and B are spread over a well-sized sheet of paper 26 x 20 inches.

Now for the most perfect form of platinotype (by any process) to be obtained, it is not difficult to see that the platinum should not form a part of the sensitising solution, but should be deposited on an image already formed, by an action similar to that of toning silver prints with gold, and for this reason no platinum in the "paper" or "printing-out" process can ever give the detail of a silver print. I have experimented with a view to a modification of the "Platino-Uranotype" process with but partial success, and it is through these experiments that I arrived at what, so far as I can ascertain, is a second novel process—"Mercurio-Uranotype." This is the title which I have given to this second process, which may turn out to be useful for rapid proofing of negatives, if for nothing else, for the tone is not very objectionable, and if preferred may be modified. Paper is coated with one or other of our uranium solutions, to which has been added some saturated solution of mercuric bichloride (say one part mercury solution for every eight of the uranium solution). A sheet of paper is coated with about one hundred and seventy minims of this solution and dried in the dark. It is then printed behind a negative until it attains full strength, which will take only a few minutes; it may then be floated on solutions of gold or platinum to obtain a more pleasing tone, and next placed in water acidulated with HCl, or the toning omitted and the print treated as if it were Pizzighelli paper. Thus it will be seen that this process is one of the simplest known.

In conclusion, then, may I venture to say that if more attention were directed to the salts of uranium many latent and valuable properties would in all probability be discovered; their reactions are very powerful and should be more generally known than they are at present. I believe much remains to be discovered in this direction.

As to the "Platino-Uranotype" process, the rough prints I have here will afford proof of my success in obtaining pictures in platinum black by novel means; and I may tell you that throughout my experiments with this process I checked results by treating prints on plain uranium paper in the same manner as the others, in order to make certain that the appearances observed were wholly due to the presence of platinum salts.

ALLEYNE REYNOLDS.

PHOTOGRAPHS TAKEN WITH THE EYE, AND THE EFFECT OF A BROMIDE PLATE IN A VACUUM AND UNDER PRESSURE.

[A Communication to the London and Provincial Photographic Association.]

By way of preface to the subject I am about to bring before you to-night, may I ask if you have ever seen anything with your eyes shut? And when I say with your eyes shut, do not mistake me and run away with the notion that I am in any way referring to any imaginary mental vision one can conjure up in the dark. For instance, look at an object that is fairly illuminated steadily for a few seconds, then suddenly close your eyes and a similar object can be seen. I do not attempt to explain this, though it is evidently governed by some law; and it leads me at last, after no end of failures, to the discovery which is one of the subjects of my paper to-night, namely, that you can obtain a photograph with the human eye if you have a light strong enough and a plate sensitive enough. After no end of failures, I obtained an impression with the aid of an electric arc lamp, 2000 candle power, which I have at my place, 92, Piccadilly, for taking photographs. I looked at the arc light for fifteen seconds, then switched the light off and exposed a very quick plate (a plate coated in different layers, which makes it much more sensitive) and held it to my eye for a minute or more. On developing it I found a spot, which pleased me very much. If you put the spot under a powerful microscope you can see the image of the arc. I have obtained marks with the magnesium flash light, but they are not so good as with the electric arc; in fact, there is nothing definite about them.

I have my flash light here, so if any of you would like to try the experiment I shall be very pleased to watch the proceedings; for I begin to value my eyes more than I did at first, because after one experiment I did at Piccadilly I had a black spot hovering about the retina for some days. With Mr. Debenham's advice, and that of others, I have come to the conclusion that it is dangerous; and the black spot did not go off until I put a piece of red glass before the arc light and looked at it for two minutes, which seemed to counterbalance the effect. I shall not try it many more times, for, after all, sight is very precious. I have only chanced one eye always, but it may affect the other, so I intend to be careful.

I may say here just one or two things with regard to the eye. It is by it we alone can judge, not only of its own perfection, but also of the comparative value of any given optical combination. It is endowed with considerable freedom of motion; and no doubt we shall have to go to the eye for many optical hints. I may here say the retina is a transparent substance composed of nerve fibres spread out into a thin layer, and corresponding to the ground glass of the camera. The retina receives the picture from the object in front, and being connected with the optic nerve behind, the picture is conveyed to the brain. I believe if one could analyse them there are salts in the retina corresponding to those used in photography, though probably of a much more sensitive nature; and the electric magnetic effect of light conducts to the brain, where there is always an alkali and acid to develop, and the atom deposit in the cells can be called at will to answer our memory. Perhaps I am going a little too far, both for myself and others who may think in a similar way, also for those who do not think in the same way; but there is no harm in giving you my thoughts, as it seems to me we like dabbling in ideas that are a perpetual mystery.

But now to offer some suggestions with regard to the picture produced by the eye. Can it be reflected from the retina, from the cornea, or from the back surface of the lens? Is there a kind of phosphorescence which can affect a photographic plate? Is it some kind of electric phenomena, and our latent image a galvanic action? Of course, these suggestions are very wild; for I must confess, although I discovered the effect, I cannot explain it, and the more I try to do so the more ignorant I feel. It may lead to something important as time rolls on. Photography is now making huge strides; its history becomes a clueless labyrinth of confusion and uncertainty; it has vigorous health and plenty of practical and mental ingenuity always at hand, which affords ample proof of the earnestness with which experimental investigators work. Experimenters should work out their internal nature, with the aid of experiments, of things contained in the varied world around them, then they will have something original to tell us, and be continually adding atoms to the progress of our fascinating art. I know, for my own part, I have formed a love and veneration for photography—with all its worry, disappointments, &c.—which has almost the nature of a passion; every act of seeing leads to consideration, consideration to reflection, reflection to combination, and combination to ideas which ought to be worked out with method and system, then we shall be sure to discover something quite new and original, especially if we work earnestly and patiently.

I must here confess that a mere statement of conclusions without the experimental evidence is of no use. I know I have gathered much knowledge from the classes that I attended at the Polytechnic and the Firkbeck Institutions. These helped me to appreciate the lectures and discourses at the Royal Institution, which I have attended the last two years, both in the afternoon and evening. I have to thank many friends for giving me passes to hear the Friday evening discourses, which are unique, varied, and leave plenty of scientific food for any one to digest.

Now with all this there are three important indispensable things we must be able to command, viz., time, money, and knowledge. Well, let us take the first. I wrote to your worthy secretary that if I waited for a convenient time to give this paper, I should never have the pleasure of interesting you in the way I hope I am doing. The same thing occurs with the use of money. If you want a thing and cannot afford it (well, if you wait until it is convenient, you will never get it all). I know it's very wrong, but I buy things and get as much credit as possible, and, strange to say, all are usually most accommodating. This little incident occurred last year to me: I know a hard-working clever mechanic at Bath, who, sometime ago, suggested this kind of pump, so I said make me one (of course I saw something in his suggestion), and I hope it won't cost more than 10*s*. He said it should not. I paid him and kept those that were richer waiting. But listen what was the result. He made the pump, got a medal for it at Falmouth, also numerous letters from mining agents, and no doubt, it has increased his trade, so this has done him a good turn, and the richer people I kept waiting ought to be very much obliged to me; and now I understand he can improve on this one. But what has it done for me? Ah! there is no knowing; you would not have had the latter part of this paper—and there is no knowing what more it may do.

Then, again, take only a few of the instruments. This spectro-scope with the Grubb lens inside (which is unique) was no end of bother to get right. Practical experience combined with a little scientific knowledge must be possessed by those who experiment with the simplest instrument. I must make an open confession to you, I cannot carry on these experiments with the system and method I

should like, so I must leave that for others who have more time and more apparatus at their disposal; but I can occasionally bring forward results which give a great field for experimentalists, though I must confess one thing—if any one had gone through with every possible care and patience Becquerel's experiments, combining method and system in every step and after all obtained nothing, I don't envy him the trouble, for after spending 60*l*. and no end of time I could only obtain two colours—but mind you, I must say this, it has led me to other experiments, possibly more important ones, so I have not lost by it. In due time I shall bring my experiments in connexion with orthochromatic photography before one of the societies. This I have thoroughly worked in a systematic and methodical way, and I am determined to carry on these experiments with a perfect method as long as I live. Capt. Abney has begun in the right way. I hope he will forgive me for mentioning his name, I only wish we had a few more like him, although not always agreeing with him, for I object to his theory of the latent image. You must not think that I do not admire and appreciate his last important communication to us, although one could wish he would take into consideration the colour which the film absorbs; also the colour of the deposit of the developer he uses. I shall always agitate until we photographers know more about the latent image than we do at present. I remember reading about Ruskin saying, "a milkmaid did not know how to make milk." Now that cap fitted me, and ever since I have been determined to know what it is we use and how to use it; and through making that determination I have been led to notice the *how* and *why* of everything except such *whys* and *hows* as these: *Why* is electricity in the clouds? and *how* is electricity formed in the clouds? Well, I'll leave you to discover.

Now to the effect of a bromide plate in a vacuum and under pressure. I must first relate my experiment. I get this air pump and an air-tight glass box such as the one I have here. After getting as good a vacuum as possible, expose half the plate to the spectrum (why I always use the spectrum is, that I may notice something in connexion with the colours), taking care to cover the other half of the plate up during the exposure. Now let in the air and expose the other half exactly the same time, of course not forgetting to cover up the half that has been exposed. You will find, on developing, the half that was exposed in the vacuum has more deposit upon it. Now I repeat the experiment, only having pressure instead of a vacuum, and, strange to say, it leaves more deposit where the exposure has been in pressure, which is very remarkable. Now I expose one in a vacuum, and instead of normal air, as I did before, I used pressure, and, strange to say, pressure has more deposit. This is very curious; I should have thought the vacuum would have had more deposit, or at least been acted on most.

I can only account for it in this way: In pressure you have heat, which accelerates; and in vacuum you have cold, which retards. Here are the results. I can at present only say this—you have the results, but not the experiments, worked out properly. I intend to do so. Here is a gauge which I intend to have fitted to my pump to enable me to give you more accurate details as to measurements, &c. In the meantime, I wish some of you would try the same experiments, and let me know the results, as I am under the impression these experiments are very important. There is another experiment I have made: filling my glass box with oxygen supplied from Brin's cylinder, and exposing a plate in it: afterwards repeating the experiment, only I used hydrogen instead of oxygen. Which do you think had the most deposit with the same exposure? Why, hydrogen. I also tried chlorine gas, but nearly got suffocated, so I cannot give you the result, and can only suggest this—I should like some one else to try this experiment.

FINESE GREENE.

PHOTOGRAPHY IN RECENT NOVELS.

II.

THE cry is, "Still they come!" My researches at Mudie's—carried on in the most philosophic spirit, as if I were engaged in deciphering the latest cuneiform inscription—seem to show that most of our novelists have recently been engaged in a profound study of the black art.

Some use it only incidentally, though with striking effect; while in other cases—as in the book of which I am going to give some account in this article—it forms the staple of the story. It is evident that the bibliographer of photography, Mr. Jerome Harrison, will have to form a new class in his lists for "photographic novels." All this shows the increasing popularity of photography, and these additions to our literature ought to be a source of pleasure to all who are interested in the art-science.

In *The Romance of a Shop*,* by Amy Levy, the story is told of four sisters whose father dies suddenly, leaving them with no resources but a few hundred pounds. The first chapter finds them in the conservatory attached to their parental home.

"The interior of the great glass structure would have presented a surprise to the stranger expectant of palms and orchids. It was fitted up as a photographer's studio.

"Several cameras, each of a different size, stood about the room. In one corner was a great screen of white-painted canvas; there were blinds to the roof adapted for a shutting or excluding the light, and paste-pots, bottles, printing frames, photographs in various stages of finish—a nondescript heap of litter—were scattered about the place from end to end."

Photography, it seems, has been the amusement of the young girls, and they determine to now make it their business, instead of accepting the proffered charity of their friends. During the discussion on this question we are told that—

"Gertrude plays nervously with a copy of *THE BRITISH JOURNAL OF PHOTOGRAPHY* which she held,"

and declares that she has a

"Plan to propose to you all. There is one thing, at least, that we can all do."

"We can all make photographs, except Fanny," said Phyllis, in a doubtful voice.

"Exactly!" cried Gertrude, growing excited, and walking across to the middle of the room; "we can make photographs! We have had this studio, with every proper arrangement for light and other things, so that we are not mere amateurs. Why not turn to account the only thing we can do, and start as professional photographers? We should all keep together. It would be a risk, but if we failed we should be very little worse off than before. I know what Lucy thinks of it already. What have you others to say to it?"

"Oh, Gertrude, need it come to that—to open a shop?" cried Fanny, aghast.

"Fanny, you are behind the age," said Lucy, hastily. "Don't you know that it is quite distinguished to keep a shop? That poets sell wall-papers, and first-class honour men sell lamps? That Girtton students make bonnets, and are thought none the worse of for doing so? We have thought out a good many of the details," continued Lucy. "It would not absorb all our capital, we have so many 'properties' already. We thought of buying some nice little business, such as are advertised every week in *THE BRITISH JOURNAL*. Gertrude and I would do the work, and you, Fanny, if you would, should be our housekeeper."

"And I," cried Phyllis, her great eyes shining, "I would walk up and down outside, like that man in the High-street, who tells me every day what a beautiful picture I should make."

"Our photographs would be so good, and our manners so charming, that our fame would travel from one end of the earth to the other!" added Lucy, with a sudden abandonment of her grave and didactic manner.

When the plan is submitted to the consideration of friends, some encourage, while others discourage it. A soft-hearted youth named Fred, declares that—

"I'll come every day of the week to be photographed, if I may, and so shall all the fellows at our office!"

But a strong-minded aunt opposes the plan, which is, however, carried into execution, the girls wisely securing the assistance of a certain

"Mr. Russell, the friend of their father. He carried on a large and world-famed business as a photographer in the North of England, to the disgust of a family that had starved respectably on scholarship for several generations."

A studio and rooms are taken at "20n, Baker-street," for though "There are a great many photographers in Baker-street already,"

yet it is held that

"It is the right thing for people of the same trade to congregate together. They combine, as it were, to make a centre, which comes to be the emporium of their particular wares."

Here the girls establish themselves.

"Over the street door was fixed a large black board, on which was painted in gold letters, G. & L. LONIGAN—THE PHOTOGRAPHIC STUDIO; and in the doorway was displayed a show-case, whose most conspicuous feature was a cabinet portrait of 'Fred,' looking, with an air of mingled archness and shamefacedness, through one of his own elaborate lattices of Virginia iron."

"It was necessary, of course, to buy some additional stock-in-trade, and the Mr. Russell undertook to procure for them at the lowest possible rates, a thing, on his own behalf, a large burnishing machine. The girls had hitherto been accustomed to have their prints retouched for them by the Stereoscopic Company."

* One vol. T. F. Unwin, 1888.

Some of the first work the girls get to do is to photograph studies of drapery for artists. But they are called in

"By a mere chance. It was the housekeeper who came, and we happened to be the first photographer's shop she passed,"

to photograph a dead lady, the wife of a Lord Watergate. Dismal as the task is, Gertrude accomplishes it very well.

"They are some of the best work you have ever done, Gerty," cried Phyllis, peering over her sister's shoulder. Gertrude looked thoughtfully at the prints in her hand. They represented a woman lying dead or asleep, with her hair spread out on the pillow.

"Yes," she said slowly, "they have succeeded better than I expected. Of course the light was not all that could be wished."

For young ladies with such determination to succeed, nothing but success was possible. Yet the first year sees a diminution of their little capital.

Presently, however, things improve.

"The business, as businesses will, had taken a turn for the better, and the two members of the partnership had their hands full. Rumours of the photographic studio had somehow got abroad, and various branches of the public were waking up to an interest in it.

"People who had theories about woman's work; people whose friends had theories; people who were curious and fond of novelty; individuals from each of these sections began to find their way to Upper Baker-street, Gertrude, as we know, had refused, at an early stage of their career, to be interviewed by the *Waterloo Place Gazette*; but, later on, some unauthorised person wrote a little account of the Lonigans' studio in one of the society papers, of which, if the taste was questionable, the results were not to be questioned at all."

Slide-making for Lord Watergate's lectures at the Royal Institution was another source of profit. But, of course, just as the thing was beginning to pay, these very heroic young ladies must go and get married! Two of them secure rich husbands—one being the husband of the dead lady who was photographed; the youngest, alas! "goes to the bad," or very nearly so, and is only rescued to die of consumption. But Lucy, who marries a poor artist, continues to practice her profession.

"The photography, however, has not been crowded out by domestic duties; and no infant with pretensions to fashion omits to present itself before Mrs. Jermyn's lens. Lucy has succumbed to the modern practice of specialising, and only the other day carried off a medal for photographs of young children from an industrial exhibition. . . .

"The photographic studio is let to an enterprising young photographer who has enlarged and beautified it beyond recognition."

And so the story ends, and a very pleasant little story it is. It affords a rather striking proof of the recent "craze" on the part of amateurs to blossom forth as full-fledged professionals; but it is well written, and our lady readers will, doubtless, find it especially interesting.

TALBOT ARCHER.

PHOTOGRAPHING THE NEBULÆ.

[Address given by Mr. A. A. Common, F.R.S., at the Camera Club. Mr. J. Trail Taylor in the chair.]

The subject on which I have to say some words to-night is the photographing of nebule. That is a branch of astronomical photography that one may say is quite recent. The history of astronomical photography itself is practically that of photography. The discovery, or the invention of the daguerreotype had hardly been described before it was applied to the delineation of the moon's surface. Bond, of Harvard College in America, made in 1841, if I am right, with the fifteen-inch refractor at Harvard College, assisted by Mr. Webley, an expert photographer, photographs of the moon. These were discontinued for a time, because the driving clock, which has been the bugbear of astro-photographers, prevented the work being done. With better driving clocks they were able to get better results, and views were taken of stars. Excellent photographs were made as good as those of the present day, with a single exception. The daguerreotype plate had to be exposed for a great length of time, and the want of sensitiveness crippled further efforts in that direction, and for a long time little was done. With the invention of the collodion process, astronomical photography took a new departure, and De la Rue in England, and a lot of other men whose names will be familiar to you, worked with the collodion process and produced very fine results. But it seemed as if the end of the capabilities of the collodion process was very soon arrived at. Pictures of the moon were taken, and pictures of stars down to the ninth and tenth magnitudes were obtained with the limited exposure that could then be given to the wet plate. The sun was photographed; in fact, the sun was one of the first objects which was photographed with success, but it was very soon found that the limit of the application of photography to celestial work was small, for they were circumscribed or fixed by the length of time that the collodion plate would remain moist and in a proper state. Great expectations were naturally formed when the application of photography

to celestial delineation was first undertaken, as might be expected, and those hopes were put rather too high; and when success was not obtained the revelation of feeling came, and astronomical photography suffered a relapse. It remained in that state for many years; in fact, had it not been for the discovery of the gelatine plate, which quite altered the aspect of the case, there is no doubt that photography would have been of little assistance to astronomy. But with the advent of the dry plate the whole position of matters was changed. As you know, one can expose for an indefinite time with a dry plate, and with vastly increased sensitiveness. Sir John Herschel who was an expert photographer himself, in the course of a correspondence that extended over many years, concerning the making of the four-foot reflector for the southern hemisphere, gave it as his deliberate opinion that photography would never enable us to delineate a nebula. I had occasion to refer to a memoir which was published for private circulation giving this correspondence, and he stated in this that photography might be used to get the bright stars, and might be used for the purpose of forming a background on which the artist could delineate the nebula; but another man, who wrote some very charming books on astronomy, gave it as his opinion as early as 1845 or 1846; in fact, he was speaking of the daguerreotype, and he says:—"Nor is it impossible that the planets, Mars, Venus, Jupiter, and Saturn, might be delineated in this way and objects discovered which could not be discerned by means of the telescope. It might not perhaps be considered beyond the bounds of possibility to expect that even distant nebulae might be fixed." Here was a man twenty years before Sir John Herschel spoke, who said a great deal more than Sir John Herschel did, and he said what has turned out to be a great deal of truth therein, for the distant nebulae which he thought might be taken have been taken since—thanks to the dry plate. With the introduction of the dry plate the whole of the capabilities of photography for astronomical research were altered, and it was not long before efforts were made to obtain photographs of the nebulae. One of the first men to do this was Dr. Draper, in America, who, by exposing a dry plate for a very long time, obtained what was then a successful photograph of the Orion nebula, one of the brightest in the heavens. Some of the nebulae in the heavens, of which there are three or four large examples in the northern hemisphere—the Orion nebula, the great nebula of Andromeda, and one or two of less importance as regards their size—are objects you cannot classify or describe, except as being a large, irregular mass of cloud. One can become acquainted with the general shape and recognise them in that way; but you cannot say what they are. Herschel classified them partly by their light and partly by their shape; but the smallness in nebulae is only a relative term here; the known nebulae as they increase or decrease in brightness seem to have different shapes, and when we leave the class comprising the larger nebulae, we get into the classes of nebulae in which the shape is not a cloud but a line; we get into classes of nebulae where the shape is that of a ring; and in the planetary nebulae where the appearance is that of a disc. Perhaps the better way of getting an idea of what a nebula is will be to see it on a photograph. Mr. Draper's work was perhaps the first. I had made attempts to photograph the nebulae because it was a subject I took up in 1874 or 1875, rather with a view to seeing if something more could not be done by means of such a powerful thing as photography. Mr. Draper was the first man who successfully photographed the nebulae, and since then the thing has been a series of successes, and we have got on now to such things as would have been considered marvellous only a few years ago.

I now show you some slides of the comet, taken by Dr. Gill at the Cape with an ordinary lens and camera attached to his equatorial. You cannot fail to notice the numerous quantity of small stars shown. In the old daguerreotype days only one or two of the largest would have been shown, and even with collodion they would have been considerably less in number; in fact, this photograph first brought home to me what power photography could give for delineating the heavens.

To come back to the photographing of the nebulae, there are one or two points of importance to dwell upon when we consider the importance of photographs of the nebulae in contradistinction to drawings. It is very easy to draw an object that has well-defined apertures, where the lines between the light and the shadow are extremely well defined, but to draw Orion where the lights gradually merge into shadows, it is impossible to get a good picture. The power of the observer's eye changes, and the longer he is in the dark the more he sees, and there is always a tendency to make more of the fainter points to the detriment of the brighter points, and to delineate bright stars with a total absence of nebulae near them, owing to the fact that the nebula, which is undoubtedly round certain stars, has not its effect upon the eye through the brightness of the star mass. Consequently, we get with the best intention in the world a conventional representation of a drawing. It can only be read in connexion with a drawing made under similar circumstances with the same hand and the same light. Consequently, one is prepared to see what one does see. In a very remarkable book, published by the now Director of the Lick Observatory, Professor Holden, on the nebula of Orion, there are the strangest shapes put down to represent one defined object that it is possible for the human mind to conceive. It does not matter whether they are upside down or inside out, they are all the same, and have no resemblance whatever one with another. Therefore, as representatives of the nebula they come to have any value. To make a comparison between such an amorphous object as a nebula, and make it clear to you, I will

ask that a few of the next slides should be put on. The next slide is Orion, from a drawing. Every one knows the three bright stars in the belt. The nebula is here [indicating], and it is just faintly indicated by a little brightness. This photograph was taken in 1881 or 1882 with a very small lens indeed, and it embraces a very large part of the sky. We will now take the next slide. [This is a drawing of the same object. It has been variously delineated by men during the last 200 years. This was about the earliest form. If you can bear this slide in mind for a moment while some more slides come on, and then compare it with one of the photographs, you will find, in some respects, there are some very remarkable things. Here is Shroeter's Bridge, this peculiar ship's prow business. Then there are the four stars forming the trapezium. Now we come to the advantage of photographs. I shall be glad if you will carry in mind the difference between the drawing and the photograph as illustrating the point I want to make—viz., the greater value of the photograph. This is one of two or three photographs which represent the different exposures of the nebula, my object being to get contour lines as showing the points of the nebulous mass which more nearly agree in intensity, but here we have absolutely no indication of the nebula. Here is a longer exposure [slide], on the principle that I should like to see carried out with regard to photographing the nebulae; exposures of varying lengths, so as to measure the different luminosities and be able to draw a contour map, and that is the best way to determine if there is any change of intensity. The next slide shows us more of the nebulae, this one the whole shape and form. If we can consider that between this and the last one there are several gradations, we can easily imagine that we can get many contour lines. And you can see that this and this portion are equal in intensity, a point which it is impossible to be sure of by any hand-drawing. We need not make separate negatives to get the contour lines, for if I take a photograph fully developed, showing every detail, I can make from that original negative which was fully exposed, with varying exposures, other copies which show the bright parts in their proper orders. While I am on this point, which I wish to impress upon you—that is, the enormous importance of photographs over the hand-drawings—I want to show you this other example. This is the second large nebula that we see in the northern hemisphere; that is, the nebula in Andromeda. This is a very large nebula indeed, and can be seen about this time of the year almost like a comet. There is a bright mass here with some outlying spots. If you get that in the right light you can easily conceive the centre position as a sun, and other nebulous masses revolving around it. Fancy this ring here [indicating] Saturn if you like, with a bright mass of condensation and a mass of nebulae all around it, and parts which may eventually coalesce and form a separate part. This was taken by Mr. Roberts with about two hours' exposure this year; bear that in mind for a moment. You may consider that an absolute representation true to nature of the appearance of the nebula; bear that in mind and turn to the next one, which shows the same nebula as drawn by Truebelow, a man whose capacity for drawing these things was unequalled at the time, and I question whether any person with ordinary means or extraordinary means can show so much as is shown there. Instead of showing anything like a bright mass with any indication of a spiral character, we have here only an odd-shaped character of "3." The general shape gives the impression that it is a circular moving mass of nebulae, whereas the next one does not. Supposing that a man had drawn this as carefully as this is drawn, and wished to compare the drawing of another man, which might vary in several points—that is, the other man might make a drawing which is more nearly approaching the photograph—are we to be able to say that any change had taken place between the first and the second drawing? Certainly not! We cannot with our knowledge as to how drawings do differ. But if this photograph is compared with a photograph which is taken later on with the same exposure and the same plates, they must be sensitive to the different parts of the spectrum, then we have a certain criterion as to whether they have changed or not. There is another photograph I will show you—the photograph of some nebulous nucleus of the Andromeda nebula. That part is largely extended here [indicating], and, overpowered by the great light, shows a distinct nucleus. That was the centre of the brighter portion, and it was just about here [indicating] where the nova occurred, which suddenly burst out a few years ago in such a remarkable way. I happened to have taken this photograph the year before, and I was able to say, without any hesitation, that there was not the slightest indication of a star there at that time. I should like to show you a slide taken five years ago. This is [slide] the spiral nebula which has been lately photographed by M. Gothard. Touching the spiral nebulae, of which there are many in the heavens, Lord Rosse found so many that he became infatuated with the idea that all these nebulae which were clumped together were spiral nebulae, and he did draw the nebulae, but broken away here [indicating] and there [indicating], and did not form a true spiral. He was led in his drawing to represent that as a mass of nebulous masses all sweeping away with proper motions toward the centre. This is a very faint thing, and was taken five years ago with a comparatively short exposure; but with the ten-inch telescope M. Gothard, in Hungary, has been able to show this in a most wonderful way. Every little patch here [indicating] comes out in a most wonderful manner, showing the character of the nebula, which is certainly not spiral. To hark back to the drawing, you will bear in mind Bond's picture. This is Lord Rosse's picture of the nebula of Orion, as made by a series of competent draughtsmen with the

large reflector at Parsonstown, of six feet diameter. Here they were hampered with more light but with a larger field. They had not only more light in the telescope, but owing to the greater focal length they had a smaller view, and consequently the view was reduced in angular measurement, and they could dwell longer on particular parts. This part [indicating] is only poorly shown in Bond's. It is pronounced here, and the whole thing becomes one luminous mass of light of equal intensity, and no one with a telescope would recognise that as the Orion nebula. There is one more photograph in this connexion [shown]. There is a little mass of light here which gives the impression of an hour-glass. This is the drawing of the object [shown], and you can compare it with the photograph, which makes more pronounced the objection I have to any drawings. This is such a delicate object that I was obliged to put this round to enable me to find it. It is a little plate I took of the nebula in 1873, which is represented in Herschel's drawing as a triangular nebula, and you can see its bright star with a little circular tail running away from it like the nebula discovered by the Bros. Henri. In photographing these feeble-lighted nebulae very long exposures have to be made, and in order to get the image falling on the same part of the plate consistently and persistently, it is necessary to have a good driving clock capable of working accurately, from half an hour up to even four hours, in order to get the best results. With regard to the question as to the telescope and the aperture and focal length and proportion of aperture to focal length it would be absurd to dwell too long on that here. But there is no doubt that whatever the perfection of the photographic process may be, however sensitive we may get the plates, the advantage will be always with the biggest aperture, because you can reduce the time of exposure; and consequently reduce the difficulty you have to suffer from through bad driving and other defects, and particularly bad weather to the smallest possible amount. With regard to the sensitive plate used, the grains of silver that are in the best photographs are of real size and do affect the image more or less. The image when it is magnified is a series of very large dots put in, and as the dots are of constant size, it affects the beauty of the picture, just in proportion to the size upon which the original negative is taken. Consequently, that points for the best results to the long focus where you could get an original image as large as possible, and increase the number of dots which go to form it. What the exposure will be I do not know; that is a question. With the best knowledge in the world you may come to a wrong conclusion. For a long time I thought the balance of advantages was in favour of the long telescope, but the gentleman in Hungary with a ten-inch reflector has taken such beautiful photographs of different objects, such as spiral nebulae, that I should have thought it was impossible to be taken with a small aperture. He has proved that ten inches is not the limitation downwards to which you can go for a really good photograph. Just now, it may be said, there are a great number of very large telescopes, all capable of taking very good photographs, but there is no determined effort made to systematically photograph the nebulae of the heavens. The sidereal heavens have been done for and settled by the Conference in Paris, which is, by united action, going to take them; but as to photographs of the nebulae—and there are many thousands all ready to be photographed—the Conference at Paris last year determined to leave this and other questions in the hands of M. Janssen, President of the Academy of Science in Paris and myself, with a view of forming a Committee, and if any men can do anything to increase our knowledge of what can be done in any way as to choice of plates or manner of development, it would be of the first advantage to us astronomical photographers to know. I think I have said enough about nebula photography, but before I finish I should like to show you one or two photographs as illustrating how celestial photography in itself has been modified by the invention of bromide plates. It is to that, and that only, which we owe the great advances that have been made; and I have one or two slides which I shall pass upon the screen, and speak upon as briefly as I can. This is a photograph of Jupiter [exhibited] taken in 1879, when that very remarkable red spot was on. You see the red ball across the equatorial and the spot at the side. You will see the spots I spoke of come prominently before you, because you can all see the original images; and you can see the great granulations. If we could get a finer deposit of silver, or could decrease the relative scale of the image, we should get a much finer grain; and you will see how that is shown in the next slide, which represents a photograph of Saturn. I thought that at the time, when the work of the Bros. Henri came over from Paris, that it was one of the finest examples, and so it is to the present day, of stellar photography. Owing to the sensitiveness of the plates, the Bros. Henri were enabled to enlarge the original image, and so get what I have suggested—that is, increase the scale of the image compared to the dots, and you will see there is a great deal more sharpness of the dots. The next picture is the only picture where the collodion has a distinct advantage over the gelatine plate, and there is no doubt that for this purpose the collodion is better than the gelatine plate. In the first place, because we have an enormous amount of light, and the exposure has to be reduced to one-thousandth part of a second to get this effect. Any person conversant with the sun will know the remarkable sun spots which occur, and the peculiar aspect of the spots. We have some very fine photographs of the moon, and this is one of the finest I have ever seen except the Lick one. The moon is a thankless thing to photograph. It makes a fine picture, but a useless picture, for I do not think our knowledge of the moon has been advanced one jot by the finest

photographs which have been taken. The Bros. Henri have tried to apply that method of enlargement to the moon as they have to Saturn, but they are not so good as Saturn. De la Rue took the moon, and he pretty well exhausted it, and the early pictures taken by him in the early days of the collodion process are nearly as good as those taken by the gelatine process of the present time. The next picture is not a celestial one at all, but it illustrates rather a peculiar thing. In 1881 I exposed a plate to the moonlight in order to see what the accumulative effect of the moonlight was, and I got in an hour and a half or two hours' exposure, in a fairly bright moon, this picture of the house opposite. You can distinguish the lace of the curtains in the windows on the other side of the road. That strongly impressed me with the power of photography, as to its cumulative effect, in getting objects you cannot see. Unless you used the telescope you could not see them. You could not see the lace of the curtains on the other side of the road, yet they were seen by a small telescope. I want to emphasise my remarks about the comparison of photography and hand-drawing rather forcibly here. This [picture] is an enlargement from one of the maps, the best series of maps of stars that were ever done; that is Arglander's maps of the southern heavens. When I first received copies of the Bros. Henri's work I immediately sought out on Arglander's map similar portions of the sky in order to find out how the photographic magnitude varied with the estimated magnitude. If you will turn to the next picture you will see how the photograph comes out. Here [indicating] is one star, and here [indicating] is another; but instead of two or three, just look at the enormous number of stars in comparison with those on Arglander's map, and look how beautifully round and regular they show. You can see at once by casual comparison the great superiority of the photographic maps over the hand ones. This [indicating] represents about the scale, shape, and size, and about the magnitude that is proposed to be taken by the Paris Conference; so if you get a map on this scale, call this a degree from here to here [indicating] and divide it into sixty seconds, you will see with what degree of accuracy you can locate the position of any stars. They represent, practically, immeasurable dots, even on such a large scale as they are magnified now. Here are a couple of photographs I want to show you to give you some idea of the telescope used for the particular purpose. This [exhibited] is a representation of Mr. Roberts's telescope. He has done some remarkably good work in England, and I am indebted for some of his photographs to-night; and some of his latest nebulous photographs are surprising. He has an ordinary refractor telescope. [Described working of same.] I hope, gentlemen, I have not wearied you too much in this long discourse.

[The discussion will appear in our next.]

AN IMPROVED CAMERA SLIDE.

Messrs. Ross & Co. have shown us a camera and dark slide, the latter of which is remarkable for portability and efficiency. It has the usual draws for exposure, but the frame does not hinge as in the ordinary form of double slide, having simply an opening to admit the plates with their separating division.

One end of this division is provided with a gutter on each side, into which the plates push easily, and are by a light spring thrown forward under guiding points at the opposite end. Their position is now higher than it should be to register in the frame, but when they are inserted their edges bear in grooves that bring them absolutely into position. It is immaterial which way the division is turned, as the spring catch which keeps it securely in the frame is placed centrally at the opposite end to the opening. It is surprising how quickly plates may be put in or changed, there being no clips, as in folding backs, to stick or to worry the finger nails. The absence of joints leaves no entrance for light, and from the solid nature of the make there is no fear of warping, which has so often caused vexatious spoiling of films.

The contrivance is such that it is no larger than necessary to hold the plates, so that it is small and light, allowing of its being used with a special camera of very reduced dimensions and weight. This camera further possesses many good qualities. It is easily and rapidly set up, is extremely rigid, and, when closed, unusually square and free from projections. The whole is made in Ross & Co.'s best style and finish.

DEVELOPMENT BY SEPARATE SOLUTIONS.

[ABRIDGMENT.]

[A Communication to the Society of Amateur Photographers of New York.]

The following is the formula I now use:—

Solution No. 1.	
Pyrogallie acid.....	1 ounce.
Sulphite of soda (crystals)	4 ounces.
Oxalic acid	20 grains.
Distilled water	1 quart.
Solution No. 2.	
Sal soda (crystals).....	2 ounces.
Sulphite of soda (crystals)	2 "
Water	1 quart.

I have two dishes: one for enough of No. 1 to cover the plates, and one

of the same dimensions for No. 2. Soaking for half a minute in No. 1 and then developing in No. 2 proceeds regularly right along until all the plates are developed.

But I must caution the beginner to always have some old developer of the previous day at hand to start with, by adding to the No. 2 solution, else the first plate or two will lack vigour. As the development proceeds, and in case of a large batch I find the solution of No. 2 to act a little slow, or with more contrast than I wish, I pour off a little and add fresh solution. In this way I have developed thirty to forty negatives of all sizes, with one assistant, of a very uniform intensity, in less than half an hour. The plates used were Carbutt's and Cramer's. I do not see any advantage in this method to amateurs who have only a few plates to develop at a time, and can watch each one carefully; but to the professional photographer who works with pretty uniform conditions of light, and gets somewhere close to the proper exposure, it offers the most regular, cleanly, and rapid method of development I know of. In addition, it is very economical, as not over one-third the amount of pyro is used as by the regular method of developing in one solution. Each plate absorbs sufficient pyro to produce the proper result, and hardness is avoided. For cases of extreme over exposure, where "doctoring" is necessary, this method will not do, and a powerfully restrained developer in the usual style is necessary.

But I am indebted to an inquiry of a gentleman, for it induced me to try hydroquinone (which I had abandoned on account of its tendency to harsh results when development was prolonged) in the same manner, and I must say that I was surprised at the result. It gives me the best class of quick-printing negatives I have yet been able to obtain, and especially is it good for very rapid plates that have a tendency to fog. I use it now almost exactly as I have described for pyro—in fact substitute, in the formula above given, hydroquinone for pyro (leaving out the oxalic acid) and you have a developer giving better results than any formula yet proposed for hydroquinone. All tendency to extreme hardness is avoided by the method of first soaking in the hydroquinone solution and then developing in the soda solution, and the action is also much more rapid than with the old formulae. The dish in which the plates are developed (No. 2) must be kept rocking (with both the pyro and hydroquinone developers) until the image begins to assume strength, to prevent uneven development. In the first soaking (No. 1) this is not necessary. I have fully determined to adopt this method of development with hydroquinone in our establishment.

It will be observed that I have omitted both bromide of potassium and sulphate of magnesium, as they are unnecessary, because the weather now is cold enough, and the plates I am using do not seem liable to frill, and I believe in simple formulae. I have also tried the addition of phosphate of soda, as recommended by Mr. Gilder, an amateur of Baltimore, but fail to see any difference in the result. It may be there is virtue in it, but I have not the time to give a careful test. I am opposed *a priori* to complicating formula with apparently inert substances, though perhaps I may be mistaken in this case.

I think this method with hydroquinone is of importance to the profession, as it is, as I have before stated clearly, regular in results, rapid in development, and economical, as both the pyro and hydroquinone solutions will keep until used up. The alkali solution also keeps well.

D. BACHMACH, jun.

THE CHAMPION PHOTOGRAPHIC EXHIBITION.

THE medal awards of the Fine Art Society for the best pictures in the exhibition now open at 148, New Bond-street, were made on Wednesday, by a jury comprising the names of Professor Herkomer, A.R.A., R.I.; G. H. Boughton, A.R.A.; John MacWhirter, A.R.A., and others. In the department of professional photography the following are the awards:—
A. Architecture: *Silver Medal*, J. Bracebridge Hilditch (St. Paul's Cathedral). B. The Figure: *Silver Medal*, C. C. Cameron (Portrait of C. F. Watts); *Bronze Medal*, W. Crooke (A Sikh). C. Landscape: *Silver Medal*, R. W. Robinson (Snow, Hoar-frost, and Mist); *Bronze Medal*, Green Brothers (Grasmere and Rydal). D. Marine: *Silver Medal*, H. Symonds (Yachts). E. Interiors: *Silver Medal*, Richard Keene (Hardwick Hall). F. Genre: *Silver Medal*, J. H. B. Wellington (Figure Studies); *Bronze Medal*, G. T. Jones (Frame of Animals). G. Instantaneous: *Silver Medal*, F. M. Sutcliffe (Water Rate). This last picture also secured for its producer the Society's *Gold Medal* for the best professional work in the exhibition.

The medal offered for amateur work, by an outside firm, had not been determined at the time of our leaving.

PATENT COMPLETED.

IMPROVEMENTS IN THE PRODUCTION OF PICTURES AND DESIGNS ON CHINA, EARTHENWARE, AND GLASS.

No. 1751. JEAN BAPTISTE GERMKUIL BONNAUD, 39, Strand Green-road, Finsbury Park, Middlesex.—*February 6, 1888.*

THE object of this invention is to produce plain or coloured pictures and designs on china, earthenware, and glass, at a considerably less cost than painting by hand, as at present. According to this invention, I take a sheet of glass and, after having thoroughly cleaned the same, I, for the purpose of sensitising it, coat it with a solution of organic matter—that which I prefer is composed of about one hundred cubic centimetres of water, to which I add about twenty grammes of treacle or other like substance, and from about five to twenty grammes of bichromate of potash (according to the state of the atmosphere) and about ten grammes of borate of soda. The glass (thus prepared), after having been left to dry, is placed on a positive photographic print, engraving, or other suitable picture or design (rendered transparent by suitable means, such as waxing, for example, unless such photographic print or other picture or design is on glass, which I prefer), which it is desired to reproduce, with the sensitised surface next the print, and after having exposed the same to the action of the light according to the usual manner of printing from a negative for a sufficient length of time (sufficient for the light to traverse the whole of the picture), the luminous rays will have acted on the sensitised glass so as to allow of the development in the succeeding process (by degrees) of the picture by dusting on powdered metallic colours as follows.

I commence by dusting on the coloured powder to represent the general shade of the design or picture to be produced, and then I proceed in the same manner with all the necessary tones of colour; this done I fix the colours by means of a fatty composition, thus placing these colours in the same condition as those which are put on by hand in the ordinary way.

This composition consists of:—

Essence of lavender	about 100 cubic centimetres.
Fatty essence of Venice	10 grammes.
Powdered resin	5 "

This picture, which by the ordinary processes would be lost after half an hour, may be kept by this treatment for a day or two before completing. After complete desiccation this composition presents a slightly tacky coating which retains the powdered colours, or, to print my picture entirely, I dust on with a dusting brush the large surfaces, and I complete the small surfaces and the details with a small paint brush in flat tints, using with the colours the above-named fatty solutions. This finished, it is evident that on turning it over a fine painting with all the light and shade, in fact, with all the tones, is entirely completed and ready to be transferred on to the porcelain or other similar material to be decorated at one operation. The transfer from the provisional support can be effected a few minutes after the colouring, whether such colouring has been effected by dusting only or by dusting and painting combined.

In order to effect this transfer, I coat the picture with a fatty composition of collodion, so that no cracking may take place by the desiccation; the following is the composition I employ:—

Collodion at two per cent.	about 100 cubic centimetres.
Fatty essence of Venice	10 grammes.
Powdered resin	5 "

The picture, thus possessing a provisional support, I put in a bath of tepid water, where I leave it until the organic matter is entirely dissolved, after which I plunge it in a bath containing about ten per cent. of caustic potash, then wash it in clean water and place it in another bath of water containing ten per cent. of borax and five per cent. of sugar, when the collodion film, with the complete picture on it, will leave the glass, and I am thus enabled to transfer it to the china or other like material as desired, which china or other like material has been previously placed in the bath ready to receive the film when it has left the glass, and when this is fired in the ordinary way an absolutely permanent design or picture coloured or toned as aforesaid is produced.

I thus obtain a picture with all the colours which will melt with one firing and give a very fine picture.

I would remark in conclusion that I am the inventor of a previous process for which Letters Patent were granted on my behalf to Emile Andreoli, dated the 30th day of August, 1880, and numbered 3511, for "An Improved Process for Ornamenting Fictile Wares, Glass, and Metallic Surfaces," consisting of two distinct operations, viz., one for the colours and another for the impression of the shades of these colours. This process gave very beautiful results in some cases, but was defective inasmuch as it was found to be impracticable, especially with complicated subjects, on account of being obliged to transfer a photograph on to a painted "silhouette," and thus mode of proceeding necessitated much work, as the "silhouette" painted on the object to be decorated had to be mathematically correct and correctly registered on to the picture, which was impossible on curved surfaces; moreover the second coat of colour only covered the first coat already fired, and, consequently they would not mix in the second firing, but by my present invention I dispense entirely with the use of a "silhouette" process, and thereby avoid the difficulties of register, and the single firing makes a complete union of the colours.

Having now particularly described and ascertained the nature of my said invention and in what manner the same is to be performed, I declare that what I claim is:—1. The process of producing on a provisional support a complete

picture or design in colours or tones with all the light and shade, so that the same may be transferred to the china or other like material at one operation, substantially as herein described. 2. In combination with this process the employment of fatty bodies throughout, substantially as herein described. 3. The process of producing pictures and designs in colours or tones on china, earthenware, and glass, substantially as herein described.

Our Editorial Table.

FALLOWFIELD'S PLATE-SUNK MOUNTS.

How greatly a photograph is enhanced by being well mounted every one is aware. Even a photograph somewhat indifferent in itself may be made to look well when attached to an elegant card. Mr. Jonathan Fallowfield is evidently well aware of the value of a good mount, if we are to judge from samples we have received from his firm. These samples are contained in an album and attached thereto for easy reference. Each is impressed in the centre with an India tint, adapted to suit prints of every dimension, from quarter size to 15 x 12, or larger, and a sunk plate mark is impressed in each mount. They are elegant and useful.

VIEWS IN BELGIUM.

The London Stereoscopic Company.

These comprise a series of eight views taken in Belgium by an amateur, from whose negatives they have been reproduced in collotype by the London Stereoscopic Company. The size is whole-plate, and the subjects comprise views of the Palais de Justice and the St. Gudule Cathedral, Brussels; the Notre Dame Cathedral of Antwerp; old houses on the Quai at Ghent; view on the Canal, Bruges, in which its famous belfry is shown; view of Dinant, and others. The set is accompanied by a sheet containing a printed description of each picture—just such a description as suffices to impart an idea of its leading features. The whole is encased in stiff covers, from which we learn that the set sells at 3s., or four francs. They are certain to be in large demand by tourists and others who desire to possess interesting pictorial mementoes of places concerning which every one has read.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
January 28	North Middlesex Club	The Iron Room, Strand Green.
" 29	Bolton Club	The Studio, Chancery-lane, Bolton.
" 30	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 31	Halifax Photographic Club	Mechanics Hall.
" 31	Liverpool Amateur	Royal Institution, Colquitt-street.
" 31	Oldham	The Lyceum, Union-st., Oldham.
" 31	London and Provincial	Masons Hall Tavern, Basinghall-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5A, Pall Mall East, London, Mr. T. Sebastian Davis presided.

Mr. FRIESE GREENE, by means of the limelight and a direct vision prism, projected a spectrum upon a screen some four feet from the slit, and exposed to it a plate coated with a film of bromide of silver covered with a film of chloride of silver with excess of nitrate. In about an hour part of the yellow and all the blue and violet rays had darkened the plate, but a broad space in the green had not darkened. He said that green light was, therefore, good for the development of such plates, and he added some remarks about orthochromatic photography.

Mr. LYONEL CLARK had not been able to understand the latter remarks; although they were stated to bear upon orthochromatism, photography in natural colours seemed to have been meant.

Mr. W. BEDFORD said that the best chemical sensitizers in orthochromatic photography were those which absorbed the rays of the spectrum to which it was desired to make the film sensitive. If any plate would photograph the three colours—red, green, and blue—properly, the problem of orthochromatic photography would be solved; so said Captain Abney. Yellow would then be included, as a matter of course.

Mr. W. H. HARRISON said that Lord Rayleigh had experimentally proved that a suitable admixture of the pure red and green rays of the spectrum would produce a bright yellow light.

Mr. BEDFORD did not consider the pure colours of the spectrum to be absolutely necessary in experiments on orthochromatic photography, especially when a yellow screen was used. Red mixed with blue would then give the best results on an ordinary plate, because the screen used with the other plate would cut off most of the blue; this was why orthochromatic plates photographed some apparent reds worse than did ordinary plates. Captain Abney often used pigment colours in his experiments. A film transmitting red rays only would absorb those of the other part of the spectrum and be sensitive thereto, in accordance with the hypothesis for which Dr. Vogel had contended for years.

Mr. GREENE then exhibited two red glasses bought as ruby glass at a shop, and said that one was safe for developing and the other unsafe; he asked the members present to guess which glass could be trusted.

A large majority of the members declared in favour of one of the glasses, and when it was tested by the spectrum it was found that by far the most unsafe had been selected; when it was then broken and a double thickness of it used it was found to be more safe than the single piece of better glass.

Mr. GREENE next exhibited a system of three optical lanterns, one of which cast a portrait of a head constantly on the screen, whilst the other two, with their apertures more or less covered, threw images of the same head, but with different expressions of countenance upon the more permanent image. The machinery did not work very well for want of accurate adjustment, but enough was done to occasionally throw life-like motions of the features upon the screen. Mr. Greene said that he intended to abolish the costly machinery before them, as the same results could be obtained by simpler means.

Mr. GEORGE DAVISON said that with a simple oil lantern he had shown a boy climbing a ladder and then coming down again; he did not see why the same principle should not be applied to double lanterns.

Mr. HARRISON asked whether, on that zoetrope principle, he could make a face slowly open and close its eyes and show the muscles of the face slowly moving, as Mr. Greene had done now and then that evening.

Mr. DAVISON was uncertain.

Mr. GREENE only looked upon the instrument as a step to something better. He hoped to use it with the new graphophone of Edison, so that the person should appear to talk as he did in life and with the same play of features to each sound. He had found that the taking of five portraits per second of the person to be so represented would be sufficient to furnish pictures to be used in the instrument; of course the sitter must rapidly change the expression of his countenance. Mr. Greene then exhibited one of the old-fashioned tinfoil phonographs at work.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, January 17, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. J. Traill Taylor presided. There was a large attendance.

Mr. A. HADDON exhibited a specimen of absorptive cotton wool recommended by Mr. A. L. Henderson for filtering and other photographic purposes; he pointed out that, unlike ordinary cotton wool, it sank immediately when placed on the surface of water, consequently, if placed in the tube of a funnel, it would require no previous wetting with water before beginning to filter a solution. He supposed that steps had been taken to remove the natural resin of the original cotton. He added that Mr. Henderson had also suggested that magnesium powder should be incorporated with cylindrical lengths of celloid, so that definite lengths could be cut off and allowed to burn slowly for photographic purposes; in certain cases such a plan might be better than that of using the flash light.

Mr. EDGAR CLIFTON then read a circular of the Oxygen Light Company, describing a new light. He had seen the light, which seemed to be kept up by something resembling the blow-through jet with the lime suspended above it so as to throw the rays downwards.

Mr. HADDON said that, if he remembered rightly, some two years ago Mr. Warnerke introduced a light on that principle.

Mr. FRIESE GREENE then read a paper on *Photographs taken with the Eye, and the Effect of a Bromide Plate in a Vacuum and under Pressure* [see page 54]. He then exposed one of his eyes for one minute not far from a long and vivid flash of the magnesium light. Then in the dark he held his eye near a piece of sensitive bromide emulsion paper on which Mr. Debenham had marked a circle in pencil, after asking permission. The paper was then developed and an image of the pupil of the eye came out strongly on the paper, a little outside the ring, which, Mr. Greene remarked, he could not see in the dark.

Mr. A. COWAN said that there was no doubt as to the fact of the eye having thus produced a photographic effect.

Mr. GREENE then put a sensitive bromide plate in an air-tight vessel with plate glass sides and furnished with a stopcock. He exposed half of it to the rays of the spectrum under the normal pressure of the atmosphere and afterwards the other half to the same light and for the same time in a moderately good vacuum; the latter half, in the same developer, gave a more intense image than the former; hence, he argued, the sensitiveness of such plates varies with changes in barometric pressure.

Mr. W. E. DEBENHAM was of opinion that the result might possibly be explained by the hypothesis that the vacuum removed a trace of retarding bromine set free by the action of light, and that Mr. Greene's statement that such plates were more sensitive in hydrogen than in oxygen might possibly be accounted for in the same way.

The CHAIRMAN thought that the phenomena of persistence of vision had something to do with the effects shown in the eye experiment, and that the light which reached the retina might, therefore, be given off again; the eye was a lens, and it was simply a case of conjugate foci. Once he was adjusting a diodescope, an invention of Bloxam for ascertaining the true time by observing the sun, he afterwards discovered that the intense light had produced an insensitive spot on the retina of one of his eyes; three or four years elapsed before the sensitiveness of that part of the retina returned. He mentioned this to Mr. Wenham, who said that he had had somewhat the same experience, but that the complete sensitiveness of his retina never returned. It was dangerous to play pranks with the eye. One plan of knowing how a picture would look when printed from a particular negative was to look through the negative at a bright light like that of the sun, then turn the gaze to a white wall; a positive picture would then be seen on the wall.

Mr. DEBENHAM did not think that persistence of vision had anything to do with phosphorescent effects on the retina. If it were merely a case of conjugate foci the outer focus should have been as far off as the original source of light.

The CHAIRMAN replied that the eye was adjustable to a certain extent, and that might have shortened the focus; it was analogous to the effect produced by a rack and pinion.

Mr. HADDOX believed that the focus of the eye for parallel rays was about three-quarters of an inch, and that to produce the effect exhibited by Mr. Greene it would have to adjust to about three-eighths of an inch; he did not think that the eye could adjust itself to that extent. The exposure in such experiments might, perhaps, be reduced by applying to the eye a solution of stramonium or of belladonna, which would dilate the pupil and enable it to take in more light. A German had stated that in the retina of the eye is much visual purple which is bleached by the action of light, so that actual pictures are printed thereupon. Professor Gangee repeated the experiments; he kept a rabbit in a dark room with its eyes bandaged, then unbandaged one of its eyes so that it should look at a brightly illuminated window; the head of the rabbit was then instantly chopped off and the eye examined by yellow light; the retina bore a fine image of the window. It was once popularly thought that the eyes of murdered persons preserved an image of the murderer, but Professor Gangee proved that the other eye of the rabbit was sensitive after death, consequently, that a previous image would be obliterated by later ones. The relief afforded by a shady lane on a bright day was due to the shade allowing the restoration of the visual purple. In persistence of vision the same image is usually repeated again and again.

The CHAIRMAN said that the brightness of the light would make the pupil contract so as to act like a small stop, which would give greater latitude in a case of conjugate foci which he had suggested.

Mr. DUBENHAM thought that there was less danger with magnesium light than with the electric light, so wished that Mr. Greene would repeat the experiment whilst some of those present sat with their backs to the light, their eyes closed, and their hands over their eyes; then in the dark they should quickly turn round and ascertain if they could see any phosphorescence in Mr. Greene's eye.

Several members objected to this because of the lateness of the hour.

Mr. J. H. R. WELLINGTON, in relation to Mr. Greene's statement that red light had restored his eyesight, said that Professor Dewar had performed an experiment in which red light had obliterated the luminosity of a phosphorescent tablet.

Mr. DUBENHAM said that red light would diminish one kind of phosphorescence and set up another kind of its own.

Mr. WELLINGTON had tried it and found that the red extinguished all phosphorescence.

Mr. W. H. HARRISON thought the meeting should not close without photographers being cautioned against repeating Mr. Greene's experiments in any shape or form. Some workers in electricity had been rendered totally blind by looking too much at strong lights; the evil done was not known at the time, but developed very slowly in the course of months.

Mr. F. A. HADDOX, Hon. Secretary, hoped that Mr. Greene's eyes were not seriously injured; time alone could show. He moved that the meeting should give him a hearty vote of thanks for his interesting paper. "Finesse jolly great fellow."

This was passed with acclamation.

Mr. GREENE thanked them for the close attention with which they had followed his remarks, and was glad to see the interest in them exhibited by the good practical men before him; he hoped to bring other experiments before that Association. He had learnt much from Mr. Haddox's remarks, and did not agree with him in all; but would not enter into controversy with him, as that would make him feel Finesse all over. As to the effect of small stops, he had noticed when looking through the smallest aperture of Wollaston's line splitter that very near as well as distant objects appeared sharply defined. In the experiments of that evening he did not object to Mr. Dubenham having done the ring on the paper.

CAMERA CLUB.

On Thursday, January 17, Mr. A. PARULES gave an address on Photo-micrography. Sir George R. Prescott occupied the chair.

Previous to the lecture a new camera by Messrs. Watson & Co. was shown and described.

The lecturer dealt with the practical portions of photo-microscopic work in detail, and pointed out the great advantage accruing to any microscopist who worked his science photographically.

Messrs. Nelson, Smith, Beck, Evans, Davies, Hocken Hepburn, and others, added to the discussion.

Mr. Fringle illustrated his lecture with a number of fine prints, and a goodly collection of apparatus by Messrs. Baker, Beck, and Watson, was lent for the occasion.

On Thursday, January 21, Mr. Graham Halfour will read a paper on *Figure in Landscape and Genre*.

CROYDON MICROSCOPICAL AND NATURAL HISTORY CLUB.

At the meeting of the Photographic Section of the above Club, held at the Public Hall, Croydon, on Friday last, January 12, Mr. Kenneth McKean presiding, an exhibition of one hundred slides by the Wollastonytype process was given. The slides were made by Mr. George Smith, and were much admired. Numerous slides made by members of the Club followed.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

A LARGE number of members of the above Association held their usual fortnightly meeting on Monday evening, January 21, the President (Mr. Henry Sandy, I.D.R. Edin.) presiding.

Four new members were elected.

MR. M. TUCKER gave a practical demonstration on *Endymion's*. First, he illustrated the use and abuse of the background as applied to photography, showing, by means of a quantity of diagrams, in what relation the background should be to the subject, and vice versa. After which he proceeded to sketch, and afterwards fill in, a landscape view selected by the company, explaining as he proceeded the different methods of treating the colours as to mixing and applying. The progress of the work was watched with interest, the time

occupied being about sixty minutes, the lecturer having succeeded in bringing out a very effective landscape.

During the evening Mr. T. Carnell exhibited some prints taken by the flash light, Mr. A. Middlebrooks had some very fine transparencies made by the transferotype process, and Mr. R. S. Arncliffe had on view some very fine enlargements on bromide paper.

A vote of thanks brought the evening to a close.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY.

At the meeting of the above Society, held on the 17th instant, Mr. George Hankart occupied the chair.

Two members were elected.

The accounts for the past year were presented by the Hon. Treasurer, Mr. W. Sculthorp, showing a balance in hand of over 11*l.* and several unpaid subscriptions yet to come in.

Votes of thanks were passed to the President, Treasurer, Committee, and Hon. Secretary for their past services.

The election of officers was then proceeded with, resulting in the following gentlemen being elected for the ensuing year, viz.:—*President*: Mr. George Hankart.—*Vice President*: Mr. S. S. Partridge.—*Committee*: Messrs. W. Sculthorp, W. T. Tucker, J. Weatherhead, and A. W. Wilson.—*Treasurer*: Mr. W. Sculthorp.—*Hon. Secretary*: Mr. H. Pickering.

It was decided, after discussion, that the lantern slide competition for the silver and bronze medals of the Society take place at the next regular meeting of the Society, on Wednesday, February 13, the slides to be delivered to the Hon. Secretary twenty-four hours before the exhibition.

It was also decided that the general competition for the silver and bronze medals of the Society for outdoor work take place on Wednesday, March 13, prints to be delivered to the Hon. Secretary twenty-four hours before the time stated for competition; and arrangements have been made for the prints to be on view at the Old Town Hall during the afternoon and evening of the date stated.

A few experiments in flash-light photography were then conducted by the Hon. Secretary, resulting in a well-exposed negative of the President, with Veeer's magnesium burner.

The meeting then adjourned until February 13.

DUNDEE AND EAST OF SCOTLAND PHOTOGRAPHIC ASSOCIATION.

THE fourth monthly meeting of the Session 1888-9 was held in Lamb's Hotel, Dundee, on Thursday, January 10, at eight p.m.,—Mr. John Robertson, President, in the chair.

Two new members were elected and one nomination for membership received.

The desirability of acquiring rooms for the Society having been brought under notice at a recent meeting, a committee was appointed to look out for suitable premises and report. This report was ordered by the December meeting to be printed and circulated amongst the members along with voting cards. Only about half of the members voted, and, as the question involved a considerable outlay annually, it was moved and seconded that the report be left on the table.

Messrs. Sturrock and Macdonald gave a demonstration of lantern slide making by the wet process. A first-class slide was produced by reduction from a 7½ × 5 negative, a powerful Argand burner being the illuminant, an exposure of five minutes being sufficient. Another successful slide was then made by contact. The prepared plate was laid on the floor between two pieces of stick, such as two matches, slightly thicker than the glass, the negative resting on these, though not touching the plate, was near enough to give a sharp slide. Two inches of magnesium ribbon burned about four feet from the negative gave a sufficient exposure.

Correspondence.

Correspondents should never write on both sides of the paper.

DALLMEYER'S PATENT DIAPHRAGM SHUTTER.

To the Editor.

SIR,—The title and contents of the letter you publish in your issue of the 18th instant, from Mr. C. Purcell Taylor, are entirely false except in that I treated his communication to me personally in the significant manner that I have a quantity of his other correspondence.

Mr. Taylor was employed by me from the commencement of February to July 9, in last year, 1888, when he left me suddenly.

I have worked for some years past, both independently and in conjunction with Mr. Francis Beauchamp, mechanical engineer, on the subject of instantaneous, diaphragmatic, and other shutters, most of the mechanical details having been carried out at Mr. Beauchamp's own works.

In connexion with this shutter preliminary patents were taken out, No. 5303, April 22, 1887, and No. 8711, June 16, 1887; these are practically incorporated with some improvements in patent No. 5619, April 16, 1888. Every detail in this letter was completed before I even knew of the existence of your correspondent. My factory "time-book" shows that on January 25, 1888 (just previous to Mr. Taylor's engagement), a large example of this form was in working, being a facsimile of the model completed before the end of 1887 at Mr. Beauchamp's works, my main endeavour at this time being to reduce the weight and bulk of the regulator. During the last month or two that your correspondent was in my employ he has himself on many occasions endeavoured to explain this identical instrument to inquirers at my office!

There are several persons to whom I showed the final form in confidence before the end of 1887 who could, I feel sure, corroborate my state-

ment were it necessary. However, I have stated undeniable facts in their order with dates, and may add that the patent agent employed for patent No. 5619 had the particulars and drawings in hand in January, 1888.

Your correspondent knew nothing of the principle or construction of photographic shutters except what was explained to him and shown him here, and his statement is as feebly ludicrous as it is, on the other hand, scandalous.—I am, yours, &c.,
THOS. R. DALLMEYER.
25, Newman-street, W.

To the Editor.

SIR,—Having seen in your JOURNAL of January 18, 1889, a letter titled "Taylor's (not Dallmeyer's) new Diaphragm Shutter," No. 5619, April 16, 1888, patented by Messrs. Dallmeyer and Beauchamp, will you kindly allow me space to state that I have now in my possession the first one that was made of the above-named invention in its rough state? It was made by me in the latter part of 1887, and was tried by Mr. Dallmeyer and myself at that time. We decided to make a well-finished one for the then forthcoming exhibition at the Crystal Palace. I have also correspondence concerning the same; this was long before Mr. Taylor was heard of in Mr. Dallmeyer's employ. In fact Mr. Dallmeyer and myself have been engaged from time to time discovering and making various improvements in shutters for the last five years, some of which we have patented and some we have not.

This is the first I have heard of Mr. Purcell Taylor being an inventor; I understood he was a clerk to Mr. Dallmeyer. He is a stranger to me, having only seen him when I have called on the firm.

In conclusion, I am bound to say that it is the most impudent allegation that I have ever heard or read of.—I am, yours, &c.,

High Cross, Tottenham, January 19, 1889.

FRANCIS BEAUCHAMP.

THE FLASH LAMP.

To the Editor.

SIR,—Referring to some remarks respecting the use of Argand burners for flash light, contained in an article headed *The Commercial Aspect of the Flash Light*, and which appears in your last issue of the JOURNAL, the author, Mr. T. N. Armstrong, says,—

"They all" (flash light apparatus and lamps of various makers), "however, start from the point which we, as an Association, were the first to discuss, viz., the blowing of the magnesium powder into some flame or other, and so produce a flash of intense actinic light. In several instances I notice that attempts have been made to claim patent rights for such lamps, and quite recently I read in the columns of a photographic paper that a certain maker had actually prohibited others from employing an Argand burner for the purpose of yielding this light. All I can say is, before I brought the public acquainted with the magnesium flash light I had experimented with an Argand burner, and gave over using it because I knew of a better means of getting the flash."

In reply, as patentee of the Argand flash lamp apparatus, and as one of some experience in artificial light photography—having been for years experimenting with various photographic lights, among which are included Moult's photogen, lexograph, P. M. Law's gas light, magnesium ribbon, magnesium burnt in oxygen, magnesium ribbon combined with limelight, magnesium and sand dropped through flames of gas, Gardie's and other similar magnesio-potash flash light mixtures—I would say that the writer of the article is wrong if he thinks that he or his Society were the first to introduce the flash light, for it is a fact—not generally known, perhaps—that this magnesium light was introduced some twenty years ago by Mr. J. Traill Taylor, and was then soon dropped, owing to the non-existence of rapid gelatine plates and to the great cost of magnesium at that time. Then, again, flash light was introduced many years ago in the process of dropping magnesium powder mixed with sand through gas flames, the rapidity of the flash being regulated by the quantity of sand used; then, still more recently, the process was revived about two years since by Herr Gardie's introduction of his flash light mixture. To these two latter systems, combined with the remarkable reduction in price of magnesium, I owe my idea and encouragement to construct and introduce my flash light apparatus; indeed, I had worked out and was commercially using for everyday work a flash light process months before the subject was discussed or introduced by the person or Society referred to.

With respect to the validity of my patent for Argand flash lamps, I venture to say that although the writer of the paper may have used and discarded an Argand burner, such use (even if employed in the same way as in my apparatus), without publication, would not in any way affect my patent. No doubt the burner was not used as in my apparatus, or its employment would never have been discarded, for surely the ejecting of a twelve or fifteen-grain charge of magnesium *horizontally* through a single flat flame of a sixteenth of an inch in thickness cannot possibly give such immediate and complete combustion as when the same charge is directed and shot *vertically upwards* from the centre of the base of an Argand gas flame of more than twelve inches in length; to say nothing of the great advantage gained when my apparatus, fitted with three burners, is used, each burner giving a flame of twelve inches in length; so that in this apparatus the fifteen grains of powder are divided amongst the three flames, and burnt simultaneously; thus, the charge has to run the gauntlet of thirty-six inches of solid flame. It cannot, therefore, be argued that a single flat flame less than an eighth of an inch in thickness can

possibly ignite the charge so perfectly or rapidly as is the case in my lamp. Without doubt, the Argand burner, altered, adapted, and arranged as in my apparatus, is certainly my own invention; and of my own knowledge, and of others learned in patent law, my patent is a valid one. I therefore shall certainly protect myself from any infringement.

With reference to the remainder of the article, wherein its author describes as new the use of limelight and magnesium light combined, I can say that I used lime and magnesium ribbon light together some four years ago, and again more recently, early last year, when I used my flash lamp and limelight combined. Certainly its use with magnesium is an advantage in brightening up the picture, but I found the limelight too expensive and dangerous for everyday commercial use. I now employ a row of fifteen or twenty gas jets and an extra couple of gas brackets, and so get all the benefit of the limelight, both for focussing and for brightening high lights, and at less cost, trouble, and danger also. There is no need to employ skilled labour to manage and work the limelight.

Trusting, sir, you will pardon my trespassing on so much of your space.—I am, yours, &c.,
A. JAMES.

1, Buckingham Palace-road, London, S.W., January 23, 1889.

HYDROQUINONE.

To the Editor.

SIR,—You very kindly inserted our letter, in which we endeavoured to draw your attention to the fact that your favourable comment on a new form of a lemon-coloured and permanent hydroquinone were irreconcilable with the facts that pure hydroquinone neither must be lemon-coloured, nor can it be permanent. You then added the editorial remark, that what you examined was hydroquinone, and was neutral.

Allow us to reply that, however much what you examined may have been neutral, it could not, from your very description, have been hydroquinone, but a composition of hydroquinone *plus* sulphurous acid, as it was found to be on chemical examination abroad.

To our constituents, Messrs. Schering, of Berlin, it is of importance, and so it is to chemistry generally, that designations for definite chemical products should not be applied to ulterior deviations, which any expert may produce more cheaply and as easily himself.

Requesting of your usual courtesy to find space for these lines in your next issue,—We are, yours, &c.,
A. & M. ZIMMERMANN.
6 and 7, Cross-lane, St. Mary-at-Hill, London, January 22, 1889.

[There is no doubt that Messrs. Zimmermann are strictly correct as regards the nomenclature of the chemical in question, and that the lemon-coloured product cannot be *pure hydroquinone*, any more than (*apropos* of another developing agent) sulphate of iron and ammonia is entitled to rank as ferrous sulphate.—ED.]

OWNERSHIP OF NEGATIVE.

To the Editor.

SIR,—In reference to the case of Pollard *versus* Photographic Company, I should be glad if this case were inquired into by photographers generally, as, having read the whole of the correspondence upon this subject, I am at a loss to understand how a decision adverse to the Company should have been given by an English judge. The only reason I can assign for it is that the true facts of the case have not been stated, and if the case, as represented by Mr. Bax's letter, had been placed by counsel before the judge, I feel confident the judgment would have been given in favour of the defendants.

Would it not be advisable for customers, at the time of sitting, to say whether they objected to being exhibited or not? In any case photographers should know the exact state of the law upon this subject.—I am, yours, &c.,
JOHN HARTE.

64, Kingswood-road, New Brompton, Kent, January 21, 1889.

SHAKESPEARE AND PHOTOGRAPHY.

To the Editor.

SIR,—Can any of your readers inform me as to the whereabouts of the following quotation, said to be from Shakespeare?—

"The glorious sun
Stays in his course and plays the Alchymist."

When we consider that Fabricius, one of the earliest noticers of the darkening effect of light on *tuna cornea*, or horn silver, only published his work on the metals in the year 1559, it must speak most highly for the observant mind of Shakespeare that he had learnt and gauged the significance of this fact.

I met with the above quotation on the cover of the *Photographic Magazine* published in 1864, and containing four specimen prints, which to this day are in a perfect state of preservation. We only possess in the library a single copy, that of June 1864, but if any of your readers should happen to have copies they are willing to dispose of, will they kindly notice that a "kind home" is ready for them in our book-cases, where they will be kept with due and becoming honour?—I am, yours, &c.,
Camera Club.
LYONEL CLARK, Hon. Librarian.

IVES'S ETHER SATURATOR.

To the Editor.

SIR.—Mr. G. R. Baker, in the 1889 ALMANAC, speaking of the Ives's ether saturator, says, "The application of soap after screwing up being a messy affair," &c. The instructions published by the American manufacturers call for the application of soap to the screw thread before screwing up, which is a very different and more effective operation. Mr. Baker also speaks of "retardation of pressure" through the folds of a "roll of flannel or lint." All Ives's saturators of American manufacture have a clear open passage through them—the old style through the centre of the roll, and the new style in the form of a zig-zag channel in the upper side of the roll; if properly made there is no perceptible retardation of pressure.—I am, yours, &c.,

FRED E. IVE.

Philadelphia, Pa., January 5, 1889.

COPYING PAINTINGS.

To the Editor.

SIR.—In the JOURNAL of the 11th instant, Mr. Dunmore wrote, "Pictor," in his last communication, states a truism, "that common sense is not technical knowledge." He gives this as a correct quotation of my exact words. This is astonishing—he must have been quoting from memory, and the subject had got "mixed," as I am sure Mr. Dunmore would not intentionally pervert the meaning of an opponent. I really made no such statement, and wrote no such sentence, nor anything that could be construed into such a meaning; it is diametrically the opposite of what I did state. Here follows precisely what I wrote, parts of which I now italicise: "Mr. Dunmore preaches up the value of common sense. On that point all sensible people will agree with him; it is an essential auxiliary, but it is not a substitute for technical knowledge; it will not enable a man to paint a picture or produce a photograph." Having thus set up the above imaginary sentence, he valiantly proceeds to knock it down in the following words: "But technical knowledge is in a great measure compound of common sense, and, so far as its application to this discussion is concerned, it is very certain that, without common sense, technical knowledge would be of little avail, but this he inferentially ignores." He then triumphantly concludes with "So much for his argument." The student of mental science may make what he can out of the above funny discussion with himself by the champion of common sense.

In his original article, Mr. Dunmore advocated the application of "glycerine and water or beer, leaving it moist while copying; either plan tends to equalise the surface and get rid of inequalities that would show as lighter or darker patches on the negative."

In his first attack "Free Lance" wrote, "Now it is all very well for the expert to paint the surface with beer, or stout, or glycerine, or linseed oil, or poppy oil, or anything that suits his purpose," and thus sanctioned the application, by the expert, of such dangerous articles as beer, stout, or glycerine, or anything that suits his purpose, on "oil paintings brought to be copied." But who is to decide who is an expert? Could you find one per thousand among the ordinary rank and file of photographers? Such eminent firms as Braun of Bernach, Dixon & Son, and a few others are, in these matters, experts of the first rank themselves, or they have first-class experts at their service when wanted, but they are the exceptions. "Free Lance" would not allow the "inexperienced" photographer to apply Mr. Dunmore's glycerine and beer, but he allowed him free use of the sponge and water, and expressed no dissent from Mr. Dunmore's plan of leaving it moist while copying, which a merely damp sponge would not do, and he said nothing about drying it off immediately after. When the dangerous character of this advice was pointed out he tried to shift his ground, and wrote that he meant "that all the inexperienced should attempt was to remove surface dirt by a sponge dampened with distilled water." But when a picture is sent to be photographed it is not sent in a dirty state—as regards surface dirt—for the photographer to clean it; that is not his business. Then the sponge and water application to "oil paintings brought to be copied" could be for no other purpose than that described by Mr. Dunmore and tacitly endorsed by "Free Lance."

His method of reply reminds me of the lawyer's instructions to counsel before going into court. "We have no case—abuse the plaintiff's attorney." I refuted him on every point worth notice, until at last, in desperation, he manufactured another of his perversions of what I stated, as to the relative merits or demerits of stout, water, and the Italian albumen varnish, which has stood the test of over six hundred years (as I could very easily prove), and which "Free Lance" terms "his modified egg-nog!" On the strength of his own misstatement, he asserted that I was "self-convicted of incompetence or want of veracity;" his own *ipse dixit* he seems to think quite sufficient to prove it. The question is one neither as to my competency nor veracity, but rather as to the sanity of the writer who could so foolishly assert "the thing that is not." I did not reply to *querques*, or say, in his own style, "that is a false statement," as that might have reduced me to his own level; but I reprinted the exact words which I did use in regard to stout and water, which proved how cunningly he had garbled and perverted their meaning. I pitied him and let him down gently, but I refuted him utterly by the inextinguishable light of truth. Yet he asserted in his last article, and in the face of the reader, that I

made "no attempt to disprove the charge of want of veracity or of competence." The mere statement of this glaring fact is sufficient to make his offence recoil with redoubled force upon his own head.

I have no knowledge of the personality of "Free Lance," but, from his writings, I believe that he is an able and experienced practical photographer. If this had been a purely photographic question, I should never have thought of contending either with him or with Mr. Dunmore. From the manner in which he has written himself down during this controversy, I am quite convinced that he has no knowledge whatever of oil painting as a fine art. He concludes with another misstatement about oils; but as his previous paragraph on oils was a mere tissue of ignorant assertions on a subject which he does not understand, I need not stoop to discuss it further with a writer who has deliberately perverted my sentences in the most disingenuous spirit throughout; to do so would be as useful as attempting to fill an empty barrel with water after it has had the bottom knocked out of it.

Mr. Dunmore says, "Glycerine and water is the mixture advocated." I accept his statement, but Mr. Hirst, "Free Lance," and I must have misunderstood him, as we all referred to glycerine *per se*; I understood him to mean glycerine, water, or beer. However, I think glycerine and water mixed would be more dangerous, in one way, than glycerine and water separately, for this reason, that water being much more fluid than any glycerine that I ever handled (some of it having been as glutinous as treacle), it would facilitate the passage of the glycerine to sub-pictorial regions, between the paint and the canvas, which it would never reach in its undiluted state. Water-colour paintings and oil paintings are things of a totally different nature. What would be a life-saving prescription for one man would be rank poison for another. Glycerine and water will take to paper "as a duck takes to water;" oil paintings will have none of them. In revenge—if they can get the slightest chance—they will sneak into the canvas underneath, through every crack and fissure, undermine the painting, destroy the very ground it stands on, and smash it up.

The value of moist water colours for rapid sketching from nature is beyond dispute, but I object to the employment of glycerine in their preparation. Artists' colourmen may find it convenient to use it, but it is not necessary; the colours prepared with it may *superficially* appear dry, but they are never thoroughly dry, and they have not stood the test of time. More than a quarter of a century ago I commenced an extensive range of experiments, conducted under counsel from the highest living authorities, on the manufacture and preparation of artists' colours, varnishes, oils, grounds, &c., simply for the purpose of acquiring sound practical knowledge of the materials of which pictures are constructed. These subjects have been included in the daily work of my life ever since. I prepared my own moist colours with a very little pure honey, taken from the comb by myself, thinned down with rain water and filtered. For valuable finished work most of the best artists use only cake colours of the finest quality; photographic colourists should do the same. Damp is the greatest enemy of all pictures, photographs included.

It was my privilege to attend the valuable lectures recently delivered at the Society of Arts by Captain Abney, on *Light and Colour*. In the last of the course he said, in reference to the official scientific investigations by himself and his colleague "on the permanency of water colours:" "By the process of exhaustion we arrived at the fact that it requires both moisture and air to cause the fading of these pigments. A great many are bleached entirely, thus proving if you have ozone and moisture together you get a bleaching without the presence of light at all. Here are some papers which were exposed to moist ozone before the lecture for about ten minutes. Indigo—bottom part was damped, top part left dry; the first half has faded, the other part has not. In carmine, too, you will see that where it has been damped the colour has entirely gone, the dry part is much less changed, &c. We come then to the conclusion that oxygen and moisture are sufficient for the fading of water-colour pigments, and that it is not absolutely necessary that there should be light present in order that the fading may take place." Moral—avoid glycerine and damp.—I am, yours, &c.,

PICTOR.

"HELIOPYRE."

To the Editor.

SIR.—As maker of the powder called "heliopyre," used by Mr. H. Paterson at the Glasgow Calico Hall with great success, I beg to state that no chlorate of potash was used in its manufacture, and that it would not explode with friction, percussion, or electricity. The accident mentioned in Mr. Armstrong's paper arose, not from the explosive nature of the powder, but from the stupidity of the lamp assistant throwing a lighted match behind him into a tin of powder which had the lid off.—I am, yours, &c.,

J. C. HUNTER.

99, Great Western-road, Glasgow, January 21, 1889.

Messrs. Mawson & Swan entertained, on the evening of the 16th instant, the whole of the employees of their Mosley-street and Low Fell establishments to dinner at Mr. Joel's Sale Room, where ninety sat down to a well-spread table. A vote of thanks being passed to the members of the firm, a very enjoyable night was spent, the various departments contributing to make up an interesting programme, consisting of glee, songs, recitations, &c. The evening concluded with a few enjoyable dances.

Exchange Column.

- Leicester's cycle clip for grass mat or background.—Address, W. W. Evers, Wath, Nottingham.
- Exchange 2s Dallmeyer lens for 10x8 outdoor camera with three double backs.—Address, 11, Southgate, 1, West Front, Southampton.
- Wanted to exchange, portable developing tent, print washer, and toning trays, for detective quarter-plate camera without lens.—Address, C. W. Harris, Fern Bank, South.
- Wanted, 3s Dallmeyer's, also 13x11 or 12x10 Ross' rapid symmetrical, in exchange for 2s Dallmeyer's and 10x8 rapid symmetrical. Difference in cash adjusted.—Address, J. Mallins, 14, Commercial-road, Pinlloe.

Answers to Correspondents.

- A. LEVY (Paris) will be written to privately.
- A.—Apply to F. W. Hart, Kingsland-green, London.
- E. L. W.—If the Squire lens is in good condition it is not dear at the price mentioned.
- H. KENNE.—By reducing the proportion of the meta-bisulphite the development will be hastened.
- O. E.—The various lenses named are so much alike that any one may be selected from them at random.
- W.—All we know concerning the present state of the French Exhibition was published in our last number.
- LUX.—Try bookbinder's paste. Your difficulty with glue and such-like cements would be overcome if you first roughened the surface of the glass.
- ANTHONY'S INTERNATIONAL ANNUAL.—To several querists we reply that this is a summer annual. The second number will not be issued till July next.
- K. F.—The method usually employed for separating a gelatine film from glass is to immerse the plate in water which has been very strongly acidulated with hydrofluoric acid.
- J. BODDINGTON.—The stock solution is the one in which the silver forms an insoluble, and it is to one ounce of this that the other ingredients mentioned must be added.
- AMATEUR.—A cabinet portrait lens of about eight or nine inches equivalent focus will be required. Stipulate with the dealer that you have it on trial, in case the focus may not suit your studio.
- LANCASHIRE.—1. Apply to W. I. Chadwick, the Hon. Secretary of the Manchester Photographic Society.—2. They are said to be more permanent.—3. Quite possible. There are numerous makers.
- J. INOUE (Belfast).—We have to thank Mr. Brown for a pamphlet (a reprint from the *Philosophical Magazine* for December) *On Figures Produced by Electric Action on Photographic Dry Plates*. It is beautifully illustrated.
- G. B. M.—A good reducer for an intense negative is to place it in a solution composed of three grains of red prussiate of potash dissolved in an ounce of a five per cent. solution of hyposulphite of soda. Use it as soon as convenient after preparation.
- W. T. SHEPPARD.—The only effect of employing a lens of such a focus on a quarter-plate would be that the nearest point of the focal range would be removed farther away. Of course a smaller angle of view will also be embraced on the plate, otherwise it will answer quite well, and, with full aperture, work with sufficient rapidity to be employed with an instantaneous shutter.
- F. C. (York).—Since receiving your letter we have tried lamps having various numbers of wicks, and although we obtained the greatest amount of light with a four-wick, yet the great heat engendered and care required in regulating the flame so as to prevent smoking render it doubtful if a three-wick lamp will not prove to be, on the whole, more useful, unless in the hands of an expert.
- REMOUE.—The discolouration of the bromide prints was probably brought about by the presence of some of the developer remaining in the prints when they were placed in the fixing solution, which contained free ammonia, and so caused a precipitate of oxide of iron. If, however, the cause cannot be traced to this source then there must have been something wrong with the fixing solution.
- Z. Z. Z.—1. The lenses named are quite rectilinear.—2. The narrower angled lens will serve admirably for general work; the former will do all that can be done by the one alluded to in this query, provided it be worked with a similar diaphragm, the focus in both cases being alike.—3. The marginal definition is good.—4. We believe you will not experience any trouble with the Customs authorities.

BOLTON PHOTOGRAPHIC SOCIETY'S EXHIBITION.—Conditions for Professional Competition.—A gold centre silver medal will be awarded by the judges for what they may consider the best series of six portraits; size, style, and process optional. Also, a silver medal for the landscape or marine view which they may consider the best; size, style, and process optional. All pictures to be sent in carriage paid, without any indication on packages, pictures, &c., as to who they are from. Inside, in envelopes supplied, must be the following:—In envelope No. 1, the competition sheet and P.O. Order only, signed with a motto or number. In envelope No. 2, must be the full name and address of the person sending; and also his number and motto. This envelope will not be opened until after the judges' award. Accompanying the competition sheet, P.O. Order for 2s. 6d. for each class, to cover cost of hanging and packing. Pictures must be addressed, "R. H. Abbott, Mechanics' Institute, Bolton," and must arrive not later than Monday, February 4. No picture which has previously taken a prize is eligible.

PHOTOGRAPHIC CLUB.—The next meeting of this Club will be held in the Masonic Hall, Anderson's Hotel, as a special lantern night, with music. No ordinary business on this occasion.

We have received several excellent photographs of both the exterior and interior of the Photographic Gallery of Sen. Stabilimento G. Brogi, Firenze, Napoli, Italia. The studio and its surroundings are characterised by great elegance.

SEIZURE OF INDECENT PHOTOGRAPHS IN MANCHESTER.—*The prisoners fined.*—At the Manchester City Police-court on Wednesday, John Leather (of the firm of Leather, Sadler, & Holmes, mount manufacturers and photographic dealers), William Tomlinson, William Bracegirdle, and Frederick Chambers, surrendered to their bail on the charge of having, on or about the 29th December, transmitted through the Post-office a packet containing indecent photographs. They were further charged with manufacturing, obtaining, and procuring indecent photographs for the purpose of afterwards publishing and distributing them. Mr. Cobbett, in opening the case, said that on or about the 29th of December an official who was employed at the Manchester Post-office, whose duty it was to examine postal packets, had his attention directed to a particular parcel, and, under the powers of the Post-office Protection Act, he examined it with some particularity. From what he observed he made a report to his superiors in the office, and, after making inquiries, the Post-office officials in London put themselves in communication with the Public Prosecutor. The packet which was sent through the post contained six photographs, and when the Bench had seen them they would have no doubt that to transmit them through the post constituted an offence under the Act. The Public Prosecutor, when he was made acquainted with the facts, placed himself in communication with the police in Manchester, and the matter was placed in the hands of Chief Detective-Inspector Caminada, who applied for a warrant to authorise him to search the premises of Messrs. Leather, Sadler, & Holmes, and seize and destroy any photographs which he might find there. On the 15th instant Mr. Caminada searched the premises and found there two or two and a half dozen photographs, some of them exactly the same as the photographs which had been handed in to the Bench, and six negatives, all of which were more or less indecent. Subsequently, in consequence of statements which were made to him, Caminada or another officer went to Chambers's dwelling-house, and there found about six photographs similar to those which the Bench had seen. Chambers formerly worked for Leather, Sadler, & Holmes. As the name of this firm had been mentioned, it was only just to say that Mr. Sadler and Mr. Holmes had no cognisance whatever that their partner Leather or their workman Tomlinson were dealing in these prints. Taking into account that the number of negatives did not exceed seven, and that the total number of photographs, so far as they knew, was not more than thirty, the police had every reason to believe that no extensive trade had been carried on in these prints. Therefore, the prosecution proposed that Leather, Tomlinson, and Chambers should be each fined the maximum penalty of 10*l.* and costs for transmitting the prints through the Post-office, and that they should indemnify the prosecution for the costs of the case. The other charge would be withdrawn. As far as Bracegirdle was concerned, it was his hand which addressed the postal packet, but there was not much reason to suppose that he knew what the packet contained, or, if he did, that he was anything more than a very humble subordinate. Under these circumstances, he was disposed to withdraw the charge against this young man. Bracegirdle was then discharged, and left the dock. Mr. Hockin, for the defence, said Leather had instructed him to say that neither Mr. Holmes nor Mr. Sadler was aware of the existence of these photographs, and had neither lot nor part in the matter at all. It was also perfectly true that Bracegirdle did not know the contents of the packet which he addressed. He merely wrote the address on the authority of Tomlinson, his superior. This was one of those cases about which the least said is the soonest mended. Leather had been a very foolish man. All he wished to say was that he had not dealt in these photographs for commercial purposes, but had been foolish enough, on going on his journeys, to carry a few about with him. He extremely regretted the position in which he was placed, and desired to express his sense of the courtesy which had been shown to him by the prosecution. Tomlinson had been in the employ of the firm for two or three years, and, so far as the partners knew, was a man of respectability. There was no doubt he had implicated himself in this case under the order of his superior, Mr. Leather. That being so, the Bench might make a distinction between Leather and Tomlinson. Chambers was exactly in the same position, and Leather wished the Bench to know that he accepted to the utmost the full responsibility for all that had been done by both of them. Mr. Headlam, the stipendiary, in giving the decision of the Bench, said the prosecution had dealt very leniently with the prisoners in not sending the case for trial. The photographs were the worst he had seen. Leather was the principal culprit in the matter. He was not only polluting the public with these photographs, but was bringing a reproach upon his firm. He (Mr. Headlam) was glad to say that the firm said, he believed with perfect truth, that they knew nothing about the photographs. Leather was fined 10*l.* and 10*l.* costs, Tomlinson and Chambers each 10*l.* and 2*l.* 10*s.* costs. We understand that, in consequence of the above, the partnership has been dissolved. Mr. Leather is not now in the firm, which will in future be carried on under the designation of Holmes, Sadler, & Holmes, the last-mentioned gentleman being the brother of Mr. Holmes.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1500. VOL. XXXVI.—FEBRUARY 1, 1889.

FACILITIES FOR PHOTOGRAPHING ALTITUDES.

So much has of late been said and written concerning photographing the heavenly bodies (or by whatever other name the stars may be designated) by the agency of ordinary cameras and other everyday non-astronomical appliances, that it is well to allude to a difficulty which the photographer may encounter at the very outset, and suggest means whereby that difficulty may be overcome.

When a camera stand is planted firmly on the ground the camera has usually sufficient movement in altitude to permit of its axis being directed a few degrees above the horizon, in virtue of which a building of moderate height, or a lofty mountain, may readily be brought into the focussing screen, but it is not easy to direct it to a greater altitude without incurring the danger of its toppling over.

Different, however, is the case when the object to be photographed is, say, the constellation of Orion, or any other celestial object, equally high, or even higher up in the heavens. To attempt the direction of the camera to such an altitude would be to bring it outside of the base of support and thus ensure its fall. True, much can be done by shortening one of the legs of the stand, a feat now easily accomplished when the stand possesses sliding adjustable legs, but scarcely enough for the object in question.

For the easy and effective obtaining of the end now sought for two methods may be employed, by either of which the greatest stability is ensured.

The first of these is one which we have more than once had occasion to bring under the notice of our readers in connexion with the photography of clouds, or the upper portion of a high building, but which will here bear repetition in connexion with alereal photography. The camera is erected upon an ordinary camera stand in the usual way, the legs being well spread out to insure stability, one of the legs is now grasped by the hand and pulled right through between the two others standing opposite. This limb now occupies a position diametrically opposite to what it previously did, the effect being that the camera is still in the centre of the base of support as before, and therefore absolutely steady, while the head of the camera stand, and consequently the camera itself, now stands at such a slope as easily to embrace an object at a great altitude. The angle of slope is not a hard-and-fast one, but may be varied to suit any particular requirement by the judicious adjustment of the legs. *Appropos*, this method is also useful for pointing the camera downwards, as in the case of a deep ravine or other object situated much below the standpoint. We have used it

with great success in obtaining a street scene from an upper window.

The other method consists in having a hinged board, the lower half of which is fixed to the tripod head by the ordinary screw, the upper having two straps of brass fixed to its sides in such a manner that it may be raised to any desired angle, being kept rigid by means of thumbscrews, in the edge of the lower board, which pass through a longitudinal slot in the brass bars, very much the same as the bars now in common use for effecting the awing or rigid erection of the folding cameras in ordinary use. To the upper of the two boards, which are joined by the hinge, the camera is firmly attached to prevent slipping when pointed upwards at a great inclination.

We can strongly recommend the latter appliance to every photographer, on account of the multifarious uses to which it is capable of being applied. Is it desirable, in making a transparency, that the camera be pointed upwards in order to clear the roof of an obstructing building, and thus secure the uniform light of the sky in the negative? this hinged base-board supplies the means of doing so in a most perfect manner. By it also we can grasp any fleeting cloud floating high up in the sky, nay, even the ceiling of a building on the one hand, or the objects on the floor on the other, may equally well be secured, for a range is thus obtained from the zenith to the nadir.

STANDARD CHARACTERISTICS IN NEGATIVES.

When the gelatino-bromide process was in its infancy, the standard of excellence sought for in a negative was that of the wet plate character, because, with it, every one was then familiar. It was on this account that the ferrous-oxalate developer found so much favour at that period. For the same reason it is that this developer is still used almost exclusively in many parts abroad, for in some places pyrogallie acid has up to the present time failed to oust it from the field. However, the wet plate standard is now less frequently referred to than formerly in England. Here one of the principal reasons why pyrogallol is so much preferred is the greater latitude permissible in the exposure. This is no mean advantage in our ever-varying light—a condition that does not prevail in the majority of the countries where the iron developer is still in vogue.

Hydroquinone, as a developing agent, is slowly and steadily gaining ground, and the type of negative it produces is

that of the wet plate character. Whether hydroquinone will eventually take the place of pyrogallie acid with the majority of photographers in this country we need not here discuss. Pyro has obtained such a firm hold upon most workers that we surmise it will be some time before any other developer will supersede it for general work. It is easy, however, to see, where the ferrous oxalate is still in use, that hydroquinone stands a far better chance of general adoption than it does here, because of the great similarity in the character of the resulting negative, coupled with the increased control there is over an ill-timed exposure.

In wet collodion negatives and iron-developed gelatine ones, the printing quality is dependent upon the density of the image itself, and as its tint may be considered a neutral one, colour is scarcely a factor in the case. In the case of a pyro-developed negative, on the contrary, its non-actinic colour gives it a proportionately greater printing density, consequently a thin negative by this developer—so far as actual opacity is concerned—will yield far more vigorous prints than will an iron-developed one of corresponding intensity.

The real excellence of a negative, by whatever process it may be produced, must be judged by the prints it will yield. It is not the prettiest negative that will always produce the best prints. Now it cannot be denied that iron-developed negatives are generally prettier to look at than are the majority of those obtained with pyro, and the same may be said with regard to those made with hydroquinone; yet do they print any better? We have heard some who have used hydroquinone complain that negatives by this developer, which, to judge by appearance, were all that could be desired, give but poor, flat, and disappointing prints, very different indeed from what the negative, at first sight, would lead one to expect. This is clearly owing to the more actinic character of the image—as compared with pyro—and with which they are the more familiar. In order to secure the same printing qualities with hydroquinone as with pyro, the negative must be made visually more intense, notwithstanding that the shadows may be much more transparent.

Let us glance at the characteristics of the two classes of negatives—the pyro-developed dry plate and the wet collodion negative; and with the latter, to some extent, may be coupled that by the ferrous oxalate and the hydroquinone with gelatine. In a perfect wet plate negative, the extreme shadows are nothing more than bare glass, the high lights being of very considerable opacity. The bare glass referred to in a wet plate negative is very different from what is generally understood as “bare glass” in a gelatine one, inasmuch as when placed on a sheet of white paper neither tint nor stain are visible. Now, starting with clear glass for the shadows and great density for the lights, a wide range of tones is secured, and this by reason of the actual opacity of the image. With pyro-developed gelatine negatives we commence with our deepest shadows, more or less, veiled—for it is seldom that they do not show a decided tint, and a yellow one too, when the plate is laid on white paper—and end with only a moderate degree of actual opacity. Notwithstanding this, there may be a great range of tones, but these are due to the colour of the image rather than to its density. Now the question is, Which of these types of negatives yield the best results?

Some affirm that it is impossible to obtain the same results in printing when the shadows are stained, however slightly, as when they are unobscured glass. On the other hand, others assert that equally as good results may be obtained with veiled

shadows as with clear ones, provided the image be correspondingly dense.

A practical answer to the question is this:—The majority of pyro-developed negatives have a certain amount of stain on the shadows, yet do they yield prints which, according to present taste, are all that is desired? For some purposes, however, absolutely clear glass in the shadows is a greater essential than actual density in the lights; and it is for this reason that wet collodion has so long held its own for negatives in some of the photo-mechanical processes. For these purposes it is possible that the collodion may eventually find a strong rival in gelatine and hydroquinone.

We are sorry to have to announce the death of M. Boissonnas, the eminent photographer of Geneva, in the prime of life. He had been suffering from rheumatism for some time, but not seriously. In the collodion days of photography Mr. Boissonnas achieved a world-wide reputation by his instantaneous portraiture, largely of children, obtaining expression which was the admiration of all artists. His reputation in this direction was sustained to the last. He was a man of a genial, kind, good-hearted disposition, ever ready to lend a helping hand, or do a good turn to his brother photographers, whether professional or amateur. The early volumes of this JOURNAL bear testimony to our estimation of his work.

Mr. Bewley, of Dublin, was, on Tuesday evening last, literally blown to pieces by the bursting of a bottle of compressed gas. He compressed it himself, and while it is thought that the cylinder contained both oxygen and hydrogen, nothing definite will be known until the inquest.

From correspondence in another column it will be seen that active arrangements are now being made for the Annual Camera Club Conference, which is fixed to take place at the Society of Arts, on March 26 and 27. Papers on a variety of topics will be read, and an exhibition of apparatus will take place as heretofore in the library. Full particulars will be announced later.

It is surprising that a town of the great population of Brighton should up to the present time have been content to be without a photographic society. However, one has just been started under good auspices, and with the talent in that region it will doubtless become a flourishing institution.

INDIAN ink of good quality is very expensive, but, fortunately a little goes a great way, otherwise the manufacturers of carbon tissue would find it necessary to get higher prices for their material. Recently, however, a writer to the *Chemical News* has described a method of making a new substance, which to his inartistic eye seemed to be Indian ink when it was applied to paper. He simply steeped camphor for about a day in strong sulphuric acid, heated it, and evaporated off the superfluous acid and unaltered camphor. The result was a rich black, that suspended in water remained there an indefinite time.

At the meeting of the Royal Astronomical Society, at which Mr. Isaac Roberts's most recent very beautiful photographs were exhibited, a considerable amount of discussion took place upon the question whether certain of the appearances seen might not be due to ghosts or effects other than genuine images. Judging by the report in the *English Mechanic*, the speakers were scarcely abreast of the practical knowledge possessed by practised photographers non-astronomical. We do not presume for a moment to suggest that the plates presented any but representations of nebulae—it is the discussion to which our remarks apply. Thus, though some aspects of the ghost question were scientifically and correctly treated, no mention was made of the fact that the portion of the plate receiving an image of a bright object became a radiating centre, light being broken up

from it in all directions and becoming reflected at the back of the plate on to the film again.

PROFESSIONAL portrait photographers are only too familiar with this class of reflection, too painfully frequent near the white collars or wristbands of men with black coats. Similarly, there can be no doubt that in the face itself such reflections act to the injury of the more delicate tones; but as this cannot be directly exhibited—a flare cannot be shown with the explanation that it is owing to a certain light object scattering light—it is lost sight of, and either never observed or its cause not recognised. Much of this effect, which is to be seen in all kinds of places besides portraits of gentlemen—skies and landscapes in particular, to quote a well-known instance—is obviated by the use of a thickly coated plate; a fact recognised by several plate makers, of whom some supply none but plates of considerable opacity, while others, again, send out both kinds.

We are inclined to believe that on this very account the new celluloid dry plates, if no drawbacks in practice occur in their use, will have a remarkable future. Of course, we are justified in expecting a similar effect in paper negatives, whether for transferring or not, and we do get it. Celluloid stands on different ground: the new future may see large changes in this direction. It is not to be supposed, however, that either paper or celluloid will get rid of all effects of what may be correctly termed fog, local or widely spread, arising from the presence of a bright image. Many causes go to bring about these effects.

PROFESSOR PICKERING, for the purpose of avoiding reflections from the back of the plate in certain recent photo-astronomical investigations, is reported to have used a backing of lampblack and shellac. We are at a loss to see the advantage of this compound, unless that the plates might be handled without fear of injury to the backing; otherwise, in practice, we should consider that a more desirable method would be the glycerine and gum arabic medium for holding the lampblack. True, the index of refraction of shellac more nearly approaches that of crown glass than does that of the gum, but glycerine has a lower index; and the gum might be slightly tempered with glycerine, and while rendered, with its contained pigment, more easy of removal in the after operations, and made also to exactly assimilate in refractive index to the particular sample of glass employed. We refer now, of course, to exact scientific work and its possible needs; for all ordinary photography we do not desire to add or take away from the instructions already published.

COMETARY ghosts, or, as photographers more frequently put it, halation, is not the only theoretical or practical enemy the photo-astronomer has to provide against; irregular reduction from certain unobserved centres of action being most essential to avoid, or detect if present. In the recent work of Professor Pickering, in enumerating nebulae photographed in a given part of the heavens, and comparing them with those in pre-existing catalogues, infinite pains were taken to provide against such error. The work of examining the plates was entrusted to Messrs. Fleming. Each plate was laid on an inclined plane, similar to a retouching desk used in photography, and by means of a strong magnifying glass thoroughly studied. Whenever a marking in the negatives appeared to resemble a nebula, the co-ordinates of it were accurately noted, but great care was taken to make sure that the marking was not due to a piece of dust, or a defect in the film. It was noted that some of the markings in the plates represented objects not noted in the catalogue, while, again, the catalogue gave stars that were not photographed.

ECHOES.

As Mr. Blackmore's paper on the ferrous-oxalate developer, read before the West London Photographic Society, mention is made of the deterioration of the solution of potassium oxalate in keeping, the formation of a deposit being stated to be one of the symptoms. I scarcely think there is any warrant for supposing that oxalate of potassium in solution is anything but stable, though certainly when dissolved in water containing lime salts a deposit will be formed at

once, but when this has subsided or been removed by filtration I fancy the solution may be accepted as one that will keep "indefinitely."

The two processes sketched by Mr. Alleyne Reynolds under the names of platino and mercurio-uranotype are interesting as chemical variations of processes in actual practical use, but beyond that scarcely present any features to recommend them. Neither in quality of results, nor in probable permanence, do they seem likely to rival platinotype proper, and it is very questionable whether even in point of price anything would be gained, even supposing other things were satisfactory. A similar process was mentioned, by the way, some seven or eight years ago, if I recollect rightly, by Surgeon-major Ranking, uranium being the metal reduced to form the image.

After lying dormant for at least three years we find the method of "development by separate solutions" cropping up again, this time in America. The main point in Mr. D. Bachrach, jun.'s, paper, published last week, lies in his reference to the application of the principle to the hydroquinone developer, and I hope to see this phase of the question further investigated, for the process of using separate solutions is a very pretty and useful one, if we could only get out of old grooves.

One of the advantages claimed for it when first introduced was the reduced liability to pyro stain; this in the case of hydroquinone will, perhaps, prove a less prominent benefit, but the latter agent will lend itself admirably to the process, and enable a considerable economy to be effected in the use of the more expensive constituents of the developer, while at the same time avoiding all suspicion of want of uniformity in the effects produced by repeated employment of the same solution.

Obviously in using the same solution—be it one of hydroquinone, pyro, or ferrous oxalate—for repeated or successive developments, each plate is necessarily subjected to somewhat different treatment from its predecessor, owing to the bromine liberated from the sensitive film during the process of development. In fact, at every succeeding application the developer becomes more and more restrained, and theoretically each successive plate should, therefore, receive a proportionately longer exposure, especially if the quantity of solution be small.

When, however, the hydroquinone (or pyro) is applied alone to the film no such change occurs, for no chemical action is set up. All that happens is that the sensitive film absorbs a certain quantity of the developing agent, which is sufficient for the purpose required when the subsequent application of alkali is made, and the unabsorbed solution remains pure and uncontaminated for use with fresh films.

In ordinary development but a minute proportion of the pyro or hydroquinone contained in the solution is actually employed to form the image, the remainder simply suffering oxidation and discolouration, and helping to mar the purity of the gradation of the negative. The "two solution" method should therefore recommend itself to all.

I should be glad to learn where the absorptive cotton mentioned by Mr. A. L. Henderson at the last meeting of the London and Provincial Photographic Association can now be obtained, for it has many uses in connexion with photography. Some ten years ago, Mr. Warnerke introduced a similar, or probably the very same, article at one of the London Societies, and it was then, if I recollect rightly, said to be of Russian origin, and to be produced by submitting the raw cotton to the action of superheated steam. Mr. Warnerke specially recommended it, I think, for making pyroxyline, for which it seems well adapted. I obtained a small sample at that time, but a few years later I was entirely unable to hear of it anywhere when I wanted to try it for filtering gelatine emulsion.

Mr. Henderson's suggestion of celluloid and magnesium "torches" for artificial light photography is a good one, but I expect some means would have to be adopted for giving a porous and easily combustible character to the preparation. Celluloid in the solid form, even in comparatively thin sheets, is, as a rule, very difficult of combustion, though it varies very greatly in different samples. Still that difficulty is not insurmountable, and for "time"—i.e. not "flash"—exposures would provide the illumination in a convenient and neat form.

Since I referred to the mixture of gunpowder and magnesium last week, I have performed an experiment which gives promising results. This consists in treating sawdust with nitro-sulphuric acid, forming "smokeless powder" in fact, and after thoroughly washing and

drying, mixing the result with a certain proportion of powdered magnesium. The mixture "flashes" most successfully, and should be perfectly safe. The only question is whether the two substances would remain sufficiently uniformly mixed if kept in bulk to give reliable exposures. JUNIUS.

AMERICAN MEN AND MATTERS.

MANY new photographic societies are being formed throughout the United States.

THE New Orleans Camera Club have adopted a novel method to attract winter tourists and settlers to Louisiana. They have made views of the most attractive scenery in their country, and have placed them at the disposal of the City Immigration Society.

AT a recent meeting of the Society of Amateur Photographers held at New York, so entertaining and instructive (it is said) was Dr. J. J. Higgins while exhibiting and describing his detective camera, that the meeting did not adjourn until midnight.

A POSTAL photographic club has been started at Chester, Va., with Mr. Thomas Manning as President and Dr. Max Mueller (Westchester, Pa.) Secretary.

PHOTOGRAPHIC aid is being had recourse to by Professor W. H. Pickering for the detection of nebulae. The clearer sky of America gives astronomers an advantage over their English brethren in this interesting branch of research.

A USEFUL means of clearing blue prints is advocated by Mr. F. H. Latimer, of Michigan. It is his belief that when preparing the paper commercially an inferior quality of ammonio-citrate of iron is employed, which gives a print of a dirty green colour. This he materially improved by converting it into a fine blue in the following way:—After the prints have been washed, he immerses them in a solution of oxalic acid of the strength of one to thirty, when in three or four minutes the prints will have attained the desired colour, after which they are again washed.

PHOTOGRAPHY has lately lost one of its devotees by the death of Dr. Maurice N. Miller, of New York, a well-known photo-microscopist and member of the Photographic Section of the American Institute.

AT a meeting of the Photographic Section of the American Institute, Mr. J. B. Gardner said that it was quite an everyday occurrence to produce a photographic line block—from the exposing of the plate to its being in the hands of the pressmen—in the short space of two hours. It is done by the following means:—From the negative a print is made on plain paper, a pen-and-ink artist next sketches the outlines and then, by means of bichloride of mercury, destroys the photographic impression, which leaves a line picture in black and white. From this a negative is taken, which passes into the hands of the etcher and electrotyper, and from thence to the printing press.

IT is very gratifying to know that the late Mr. Edward Anthony was so thoroughly recognised as being a universal friend among the photographic fraternity, that resolutions of sympathy have been passed at the meetings of all the various American photographic societies.

A TRANSATLANTIC editor states that a photographer in Boston has recently devised a set of gummed tickets to be pasted on the edge of lantern slides, so that their names can be read whilst they are in their storage box. This certainly is a good idea, but although seemingly new in America it has been in regular use in England for upwards of twenty years.

THE valuable collections of prints illustrating photo-mechanical printing belonging to the late Mr. J. W. Osborne have been pre-

sented to the United States National Museum at Washington and the Boston Art Museum.

THE *American Journal of Photography* observes that prints are very often overwashed in the desire to free them from the last traces of hypo. Prolonged washing gives the prints a pale look. A chemical precipitate can be washed free from foreign impurities with twelve times its bulk of water, the water being applied in small quantities and at short intervals. Bright, beautiful prints will repay any risk of fading from insufficient washing.

MR. RAU, of Philadelphia, has successfully taken some flash light photographs of a theatrical stage, and although some of the characters were in positions which were difficult to maintain, still the results produced are said to be excellent.

THE Scovill Manufacturing Company are no longer the publishers of the *Photographic Times*, as it is now to be issued by the Photographic Times Publishing Association; and the photographic department of the former Company has been purchased by the Scovill & Adama Company, with W. Irving Adams, of the Scovill Manufacturing Company, as President.

IT must be gratifying to the editor of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC to find that the editor of the *American Annual of Photography* pays him the compliment, both in the present and past year's issue, of reproducing more than one page of the matter of the Old World Annual, but without acknowledgment however.

INSTANTANEOUS WORK.

XII.

IN my last I pointed out a very common error which nearly every beginner in photography falls into when photographing such scenes as moving or running water. The belief is that because, as in the case of a fountain where the sprays and jets of water are in rapid motion, that such require an almost instantaneous exposure. The same belief extends to waterfalls, while the fact is, that such are not subjects for very fast exposures at all.

I remember one day, when being at the Bracklin Falls, of meeting in with a number of amateurs who were out as an association, and of course they soon busied themselves in the selection of the best spot from whence to take the picture. On the occasion in question some kind member of the association had promised a prize for the best picture taken that day, so a good deal of mystery and concealment of ideas, &c., regarding exposure, were practised by those competing for the prize. I could soon tell those who would not secure the coveted honour by seeing them taking the picture with their shutters. To get a good view of this waterfall it is necessary to go down into a deep cauldron into which the water rushes, or else to rig up the camera among some thick bushes on the bank opposite. Even in the best of summer days the light here is always more or less cut off by the surrounding trees and high banks, and to attempt to take such a picture by a rapid shutter exposure was sheer nonsense, yet because the water was moving a very large proportion of those visiting the locality that day actually did so. I had taken the Falls on several occasions and knew pretty well what to give, and could therefore see at once how miserably those had failed who used their shutters, but no doubt when they came to develop the plates would be blamed. In water effects the great charm is softness, and, as is well known to experienced workers, that at least one of the most important factors in the securing of the same is to give the plate a full exposure with a liberal stop, and when the development stage is reached to "caanny with the pyro;" but of development more later on.

Confined waterfalls, running streams, fountains, and such-like, should never be taken instantaneously.

Of late years the craze for instantaneous work has been so great that very many clever mechanics have spent much thought and ingenuity in so constructing a camera that will enable them to secure pictures without attracting the attention of those who are being taken, or even by those in the immediate neighbourhood when the little operation is going on; the result of this being that what is termed "detective cameras" are now made by a great many of the leading photographic apparatus makers.

To secure secrecy of action, perhaps there is nothing better yet in the form of detective camera than the original "Stirn," or, as some choose to call it, the breastplate camera. Such is easily concealed under the waistcoat, and the lens being pushed through the button-hole it is almost impossible to know when such is being used, or is in the hands of a "chiel amang ye taking notes."

In the majority of cases, however, manufacturers have struck out on different lines and put together some extremely clever sets of apparatus, most of which assume the shape of an oblong box, the necessary knobs and attachments for the firing of the shutter, &c., being easily worked by merely pressing with the finger some little protuberance on the outside of the box. Doubtless the desire to secure pictures of a larger size and more artistic shape than that obtainable with the breastplate camera has had much to do in the way of causing manufacturers to adopt the oblong box as the best means of eluding suspicion, but I am far from thinking that this black box arrangement is the best means of obtaining the desired result. In respect of secrecy and rapidity of action, the original form of "Stirn" is, in my opinion, much to be preferred, for the British public are, as a rule, not slow in casting suspicious eyes when a swell is seen strolling up and down a fashionable thoroughfare with a tall satin hat on his head, and a black or yellow oblong box slung over his shoulder. Such is not an overdrawn picture, kind reader, for the writer actually witnessed such in Glasgow the other day in one of our most fashionable streets (Sauchiehall-street). I knew at once it was a detective camera of the very latest pattern, and at first could scarcely believe my eyes. As to secrecy, there certainly was none about the swell I saw, and so I said to myself, can it be an advertisement? A few days afterwards I found out that one of the Glasgow dealers had seen the same strange gent, and, very funny-like, came to the same conclusion as I did, that after all it was an advertisement.

In the hands of a clever manipulator doubtless some nice little pictures are now and again obtained, and very often some downright good fun is to be had by using such little instruments, especially when the chief actors in the drama had no idea whatever that they were being taken; but to my mind, in a measure, all these so-called detective cameras partake more or less of the character of a scientific toy, and, in some cases, a very expensive one to boot. I wonder what is the actual percentage of good results obtained, even by clever manipulation, when using such with shutter exposures and held by hand. I don't say I have not seen some delightful little pictures obtained by such, for I certainly have been shown some wonderful results in the way of bathing scenes, &c., which were obtained by Mr. Oliver, of Glasgow; but it is not every one that can work the little instrument from beginning to end like he can. Neither do I say I have used all the different forms of detective cameras which are on the market, but I believe I have had most of them some time or other through my hands, and, therefore, pretty well able to judge of their merits; and, after all, what does it come to? Simply a camera so concealed so as not to let any one know that such is being used.

I remember one day being shown by a Glasgow amateur what is, after all, perhaps quite as good an arrangement as any, and which will work quite as well as the rest of the high-priced boxes offered to the public. This consisted merely of an ordinary quarter-plate camera, with three double backs, and a small Kershaw shutter. To convert such into a detective camera was very easily done.

From somewhere in the regions of the garret an old hand bag was ferreted out, which just nicely held the little camera. To keep the same in a fixed position in the bag a hole was bored through the bottom, through which the tripod screw was put, making the same tight by the aid of half a thread bobbin. This kept the camera fixed in the bag. Right opposite the lens, in the side of the bag, was cut a U-shaped aperture, and the whole thing was complete. Being asked to accompany my friend to try it, and so see how it worked, we quietly strolled to one of our busy parks, and, looking out for a good spot, sat quietly down on one which just nicely overlooked a path up and down which passers-by were continually moving. In ten minutes we had spent our six plates and went home. I was quite surprised at the success. We developed four good negatives. To use the camera we had to open the bag and touch the shutter, but I found the opening of this old bag to be rather an advantage than any deduction from its usefulness, for it was a very natural thing indeed for any one to open a bag and look into it for something. Such never attracted the least attention of those being photographed, and who had not the slightest suspicion of what was going on. Of course it is not so easy to manipulate as some would like, but for a makeshift outfit it works wonderfully well, and since then my friend informs me that he can get good results when holding the bag on his breast and looking down into it as if he had forgotten something on leaving home.

I know another gentleman who gets impressions with an old cigar

box slightly altered, and which he wraps in brown paper, and ties same up with a string to elude suspicion. He has shown me some of his results; but, all told, I like the old bag arrangement best.

Unfortunately, in this climate we are seldom favoured with such intensely bright light as is to be found in America and other countries, and this is the one great drawback to the use of these so-called detective cameras. Now and again a fully exposed plate is got here, but, as a rule, nearly all are under exposed, and, in the case of street scenes, some very much so. Perhaps there is hardly any place which offers such chances for a little amusement with what I prefer to call hidden camera work as on board a large passenger steamer. Here no end of impressions may be got, and but little difficulty experienced, in ensconcing oneself in a position where not the least suspicion is aroused of what you are after.

T. N. ARMSTRONG.

PHOTO-MECHANICAL JOTTINGS.—II.

THERE are various ways of making photo-transfers, viz., upon paper direct, and upon zinc, for subsequent re-transfer to stone. The direct method is that most generally used, and for rough, ordinary work answers very well; but where fine work is wanted with absolute register, scale, and size, then the zinc method must be used.

Line transfers may be pulled from collotype plates, rivaling in sharpness and scale those pulled from zinc. But they require so much longer time preparing than the zinc plates, that they are very seldom used for the purpose.

There are several ways of preparing the paper for the direct methods, each of which has its advocates. The paper may be coated with gelatine, chrome alum—a trace—and potassium bichromate, or with arrowroot and bichromate, thus making the paper sensitive with one operation. Paper so prepared is, after exposure, inked up dry and developed in hot water.

Another way is to coat the paper with plain gelatine, dry, then to sensitise by immersion in an aqueous solution of potassium bichromate, soaking the exposed print in cold water before inking up.

The ordinary transfer papers sold for carbon work, sensitised and developed in the same way, yield very good transfers.

Winstone, Shoe-lane, London, sells Husnik's transfer paper, which is sensitised in potassium bichromate dissolved in a mixture of water and methylated spirits of wine. This paper is inked up dry and developed in cold water. This paper is made by first coating with gelatine and chrome alum, drying, then floating upon albumen, which requires the methylated spirit to coagulate it and prevent its removal during sensitising.

Hank post paper is usually recommended for photo-litho work, but it is too thin. The best paper is good wove, not laid, paper, from twenty-five to forty pounds per ream.

Inking up the Prints.—The old plan of inking up the prints involves the use of a litho-press in the dark room, and is at its best a clumsy and wasteful way of doing the work. The easiest and best way is to use a board like the back of a printing frame, one portion to be, say, 12×3, and the other 12×15, hinged together; the hinges to be sunk in the wood so that when the board is laid on the table it will lie quite flat. To use this board raise the board in the middle, insert the edge of transfer in the joint, and the pressure at the hinges will hold it tight. Now on a clean inking slab thin a little photo-litho transfer ink with turpentine, charge a glue and trawler roller, then ink up the print, rolling from the hinges only, continuing the rolling until the turpentine has evaporated, when there should be a thin, even coat of ink, through which the image can be faintly seen. One of the points upon which a beginner stumbles is the inking up of dry transfers—the usual plan being to crowd on as much ink as possible, the consequence being that the print smears in development.

In inking up a wet transfer place a piece of thick blotting paper on the board. Place the wet transfer upon it face up, fix in the joint, blot the surface with either blotting paper or a soft cloth. Then having charged the glue roller with thin ink, roll the print one way only until the whites clear, leaving the lines forming the image standing out firm and black. A gentle rub with a pldget of cotton wool well charged with water will remove any scum left on whites, and the transfer is hung up to dry.

Photo-litho transfers should be dried at as low a temperature as is possible, else the gelatine coat will be made brittle, and the ink made too dry to give a solid transfer. For photo-litho transfers on zinc thinner metal is used than for etching, as better contact is obtained over large surfaces, as well as being easier to handle.

The zinc must be well polished with very fine emery cloth and turpentine, then immersed in a weak bath of nitric acid, alum, and

water—ten drops of nitric, ten grains of alum, to a pint of water. This is put into a tray, the zinc immersed, and the tray rocked until the polished surface of zinc gives way to a fine matt. The plate is now removed and well washed, the scum being removed by rubbing gently with a pledget of cotton wool. The plate is now put into a whirler and coated with albumen, then whirled, coated again, whirled again, then dried over a small spirit stove. The albumen is composed of white of one egg; water, eight ounces; saturated solution bichromate potash, one ounce. Beat up the egg, add the water, mix, then add the bichromate solution. This mixture must be well filtered before use.

To get good prints on zinc a whirler must be used. A film of albumen on zinc, well whirled, requires less than one-quarter the exposure of a film not whirled. Unwhirled films are uneven, one portion of plate having no film, and another portion having a film too thick, through which the light, not having penetrated, washes off in development.

Inking up after exposure is effected with a glue roller, charged with thin ink, care being taken to get a very thin, even coat of ink all over the plate. From these prints upon zinc the transfers are pulled on litho-transfer paper and then re-transferred to stone. The transfer to stone is best entrusted to a skilled lithographer, especially by beginners, as careless or ignorant transferring will spoil the very best photo-transfer.

Do not try photo-litho or any of the photo-mechanical processes with makeshift appliances, but get proper tools first, then the work will be easy and pleasant, and the results good.

W. T. WILKINSON.

THE DEVELOPMENT OF GELATINO-BROMIDE LANTERN PLATES.

[A Communication to the Manchester Photographic Society.]

THE time seems to have come when lantern slides can be made on gelatino-bromide dry plates which shall compare favourably with wet collodion or collodio-bromide transparencies, and shall be almost as certain in their preparation. For some time those who have occasionally tried their hands at transparency making on gelatine plates (and what amateur photographer has not?) must have felt that it was only a question of a developer, and, given that, success must be attained. Ferrous oxalate has, as our lantern exhibitions have shown, produced transparencies which have left nothing to be desired either in the matter of colour, of transparent shadows, or clear high lights; but when we have seen these selected specimens on the screen, the experienced among us have been apt to ask how many failures there have been before these casual successes have been scored. To obtain a good ferrous-oxalate transparency, I think exposure must be absolutely correct and the developer must be in exact sympathy with the exposure; the result is then as good as need be. But this happy state of affairs rarely happens—certainly, if I may suppose my own experience to be that of others, not once in twelve times. The use of sulphite of soda, or meta-bisulphite of potash with a pyro developer, joined, perhaps, to improved manufacture of plates, has made all the difference between certainty and uncertainty, and one may now calculate on getting ten or eleven good transparencies out of every dozen plates. Exposure within reasonable limits is not of such great importance, little more being necessary than to see that it is long enough.

Although I shall not be able to show on the screen any examples of transparencies from the same negative produced by three methods, I purpose showing a few developed by ferrous oxalate, and the same by pyro or hydroquinone. I shall also show some examples of wet collodion transparencies, and copies from the same negatives on gelatine developed with pyro or hydroquinone. Before showing these in contrast, I may say that I think collodion still carries off the palm; but gelatine follows so closely behind, that did we not see the two in actual contrast I doubt if we could tell one from the other. Collodion does produce, in my opinion, shadows of greater delicacy and transparency.

So far as dry plates are concerned there is no fear of going wrong; there are plenty of good ones in the market—indeed, I do not know that there are any bad ones; but those I have used lately have been Thomas's and Swan's, both of which are extremely good, the latter being about twice as fast as the former. The makers of these plates each have their own formulae, but it is immaterial which you apply to which. There is no great difference in them, except that one maker uses sulphite of soda, while the other uses meta-bisulphite of potash as the pyro preserver; both, however, give their formulae in the wholesale manner that is so exasperating to amateurs, and that requires such an amount of intricate calculation before we can see

exactly what they mean. This matter is really a very great grievance that amateurs have against plate makers in general; we do not make up our solutions by the Winchester quart, or even by the imperial pint, and our dark rooms are crowded enough as it is with only such moderate bottles as four, six, or eight-ounce. I suppose there must be some motive for publishing formulae in this annoying way, but cannot imagine what it is, except it is to throw dust in our eyes and make it impossible, unless we are mathematicians of the highest order, to see what a formula really is when reduced to its simplest terms. It is on the same principle that doctors write their prescriptions; but though it may not be very important for us to know exactly what it is that cures or kills us, when we come to the more serious subject of photography it is necessary for us to know exactly what we are doing, if we are to have any intelligent interest in our work. Why cannot plate makers tell us what every ounce of solution contains, as well as give us instructions how to make wholesale quantities?

I give now, in what I consider a reasonable manner, formulae for the pyro developer recommended by the two makers mentioned. Thomas gives in one ounce (approximately):—

A.	
Pyro	2½ grains.
Sulphite of soda	7½ "
Citric acid	1¼ grain.

B.	
Bromide	2½ grains.
Ammonia	1¼ minim.
Carbonate of ammonia	2½ grains.

Take equal quantities.

In making up the developer, I confess I have not striven in some of the ingredients for mathematical exactness. Thus, in the item sulphite of soda, I have taken as much in my hand as I thought *would do*; I have dissolved this in *some* warm water, and have taken of this solution as much as I thought would about hit the prescription to a nicety. Again, not finding carbonate of ammonia in my stock of drugs, I used carbonate of potash, which I found to suit perfectly; indeed, the developer (and all developers I have ever seen) will stand a considerable amount of modification, according to the taste or fancy of the party, as Sam Weller says. The result of development, when carried out in the conscientious manner I have spoken of, is, when dry and viewed by reflected light, a whity-brown, approaching collodion colour, with absolutely clear glass in the high lights.

Swan's formula is simpler, being—

A.	
Pyro	2 grains.
Meta-bisulphite	6 "

B.	
Bromide	2 grains.
Ammonia	7 minims.

The result by reflected light is a much redder brown than Thomas's, but viewed as a transparency the colour is much the same.

A very excellent developer is one half of which is taken from a formula given in THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1888 by Mr. Edwards. It is a stock bottle made thus:—

Ammonia	2 drachms.
Bromide	3 "
Water	4 ounces.

Of this you may use as much as you like, but after many trials I have found about a quarter of an ounce to give about the best result. My formula would then be:—

Pyro	2 grains.
Sulphite of soda	6 to 10 "
Edwards's, as above	¼ ounce.
Water, to make	2 ounces.

The components of "Edwards" will be about, in this quantity, ammonia, 6 minims; bromide, 9 grains.

Mr. Brennan, some of whose slides I shall show presently, used Paget's developer, which is in great contrast with this last-named one. In a two-ounce solution the composition is about as follows:—

Pyro	2 grains.
Citric acid	1 grain.
Sulphite of soda	8 grains.
Ammonia	1½ minim.
Bromide	½ grain.

These two developers show how wide the room for the operator's fancy is.

After development and before fixing, I put the plate for about five minutes in a solution of chrome alum, quarter ounce to the pint, and this has the important effect of rendering the film pretty nearly insoluble in hot water. Swan's film will not, however, stand the same heat as Thomas's. Two or three plates may be developed in the same solution (two ounces), and should there be any slight discolouration or deposit during development, a rub with the fingers in hot water entirely removes it. In fact, hot water is an excellent clearer and quite safe up to 110° to 120° Fahr. The disadvantage of chrome alum is that it is difficult to wash the films off the glass if you want to do so.

As well as the pyro developer, Thomas gives the following one for hydroquinone:—

No. 1 STOCK BOTTLE.

Hydroquinone	100 grains.
Sulphite of soda	2 ounces.
Citric acid	60 grains.
Bromide of ammonium	20 "
Water to	20 ounces.

No. 2 STOCK BOTTLE.

Carbonate of potash	2 ounces.
Carbonate of soda (crystal)	2 "
Water to	20 "

Take equal parts.

This gives in two ounces of solution:—

No. 1 STOCK BOTTLE.

Hydroquinone	8 grains.
Sulphite of soda	5 "
Citric acid	3 "
Bromide of ammonium	1 grain.

No. 2 STOCK BOTTLE.

Carbonate of potash	5 grains.
Carbonate of soda	5 "

This is really an extraordinary developer; it is quick, gives an admirable colour, remains quite clear in use, and the same two ounces may be used for a dozen plates, one after another. I have developed fifteen, and the last one came almost as quickly as the first and was quite as satisfactory. It is necessary to develop to a slightly greater apparent density than is required for the result; the plate clears with perfectly bright high lights, and is satisfactory in every way.

I should say that all these developers produce equally satisfactory results with plates exposed in the camera or by contact to gaslight. I do not think there is a pin to choose between them.

Now, I am sure any one may make lantern slides, and good ones, too, and by gaslight may get through a dozen in an hour easily. In the camera the process is, of course, slower, especially in weather such as we have had for some time, every one requiring with a stop of $\frac{1}{8}$ an exposure of from four to fifteen minutes.

Exposure, whether to day or gaslight, must be a matter of some uncertainty, and the best of us may have to intensify or reduce, and even those important processes may, I think, be safely carried out with gelatine plates. Before doing either, I consider it is much the best plan to first dry the transparency. I have not tried many reducers, but the safest and quickest I have found to be common chloride of lime in water. The action is almost immediate; but if the solution—or, I should say, the lime in suspension, for it does not dissolve—is not kept moving, a pitting of the gelatine takes place, which, if allowed to go on, quite ruins it. If the plate is put dry into the bleach, no alteration in colour takes place, but a marked and immediate one is visible if the transparency is dipped into it before drying, the shadows assuming a bluish colour; the transparent parts are also attacked and slightly clouded, which is not the case if the plate is put in dry.

Intensification is safe and easy, but it also should be deferred until after drying. The usual bichloride of mercury may be followed, after washing, by a solution of sulphite of soda, and the result is generally, but not always, successful. A few weeks ago a formula for intensification was recommended in the leading columns of THE BRITISH JOURNAL OF PHOTOGRAPHY which seems to be an excellent one. It is as follows:—

Bichloride of mercury	20 grains.
Chloride of ammonium	20 "
Water	1 ounce.

Wash well and tone with—

Liver of Sulphur (sulphide of potassium) {	20 to 60 grains
	to 1 ounce.

The latter substance has a dreadful smell, exactly like the choicest Marrogate sulphur water, but it produces capital tones, and great

variety of colour may be obtained from it. I think it a very useful addition to our laboratory, notwithstanding its unsavoury qualities. I may add that I think a better colour is obtained if, after washing the chloride-bleached picture, it is dried again before putting it into the liver of sulphur solution. ABEL HRYWOOD, JUN.

PHOTOGRAPHIC OBJECTIVES.

FACTS AND FALLACIES REGARDING THEM.

[Read at the Minneapolis Convention.]

THE literature on photographic optics is exceedingly meagre, and that which is open for study is distributed mainly in the form of papers and articles written in photographic journals. The terms "depth of focus," "distortion," "chromatic and spherical aberrations," and "visual and chemical foci" are used rather promiscuously, and I fear not always understandingly.

It is not my purpose to give you a treatise on optics pertaining to photographic lenses, but to mention those terms and give explanation of them which meet one in pursuit of photography, and draw attention to some things which, from my experience and a varied correspondence, I am led to believe are not fully understood by all. The diversity of qualities pertaining to lenses for photographic purposes is apt to be confounding, unless a person has the benefit of extended experience or study on the subject, and there is no question that the assumption of knowledge where it did not exist, or relying on statements which were not correct, have led to many errors of judgment, which, in turn, have been the cause of disappointments, prejudices, and loss.

I therefore think that any statement of facts which are incontrovertible, because they are natural laws, will not only be fruitful of a better knowledge, but may in time lead to some unity of action in the mode of examining and testing objectives, for I venture to say that there is a necessity for this, inasmuch as different persons follow different plans, giving varying results, and few of them accomplish the complete result.

It may be best to say at the outset what the qualities are which are involved in a first-class photographic objective, and which, with many others, are the problems for the optician to solve. They are as follows:—Exact coincidence of visual and chemical foci; a formula involving such glass and curves as will give the utmost freedom from spherical and chromatic aberration; such a relation of glass and curves as will avoid internal reflections and consequent "flare" or "ghost;" length of focus; diameter of lenses; absolute homogeneity of glass, or freedom from striae or veins; grinding and polishing the various surfaces, so that they shall be strictly spherical; absolute centring of lenses before and after mounting.

I cannot think that I can better show the importance of these various factors than by leading you through the process of completing a lens, omitting the minutiae of work, and thus, also, showing you the difficulties which beset the path of the optician in his endeavour to reach the result. We will assume that he desires to make a medium-sized objective, of the form which is principally used to-day (a system of two symmetrical combinations), and that he has laid out in advance the formula on which he intends to construct it.

He has in his possession four plates or discs of rough and unsightly glass, two of which are crown and two flint, which are to be to him the cause of disheartening failure or gratifying success. If he has any experience at all, he will use no other than such as is warranted by the glass manufacturer, because even then he will find considerable difficulty in obtaining perfect glass. The glass comes from the manufacturer with a guarantee or not; in the latter he assumes no responsibility, while in the former he does, as far as the refractive index and most glaring thoughts are concerned. If they are of guaranteed form, the discs have facets ground and polished on the edges on opposite sides, by means of which the maker has carefully tested the glass, and by which means the optician may do the same.

I would say here in parenthesis that none of this glass is produced in this country, and none of the glass manufacturers with whom we have yet come in contact have shown any inclination to undertake to make it. We hope and feel confident that the time will come when it will be made within our borders, and when so, with the natural facilities at our disposal, we feel certain that we shall obtain a higher and more satisfactory result than exists to-day. The cost of the glass is now a very important factor in the price of the lens. The glass itself must, of course, conform to the formula, and often the formula must conform to such glass as it is possible to obtain.

Any variety of crown or flint may be obtained, but it has been found that the light flints and crowns give the most satisfactory results. Flints are usually the outer lenses of double combinations, and

when heavy are exceedingly soft and subject to oxidation. The optician now begins to abrade the glasses, giving them approximately the form he wishes them to have, and then begins the process of grinding and polishing. Although this is done on the same general principle, the details vary with different opticians; and although the same result may be and is accomplished in different manners, it is safe to say that if one were to follow the plan of another he would fail. There is a peculiar touch or feeling in doing this work which it takes years of practice to acquire, and even then I find a person must be adapted to it. One might give the method of procedure down to the minutest detail, and this has often been done, and for all that a person might follow it any number of times and still fail. One thing, however, is true, that few persons have any conception of the amount of exactness which is required in this work. This remark, of course, applies mainly to an objective which is to be of the highest standard, and which, to a certain extent, varies with different opticians according to their skill, and not to such productions as may be called commercial, for the reason that the pecuniary return, and not excellence, is the paramount consideration. A certain amount of care is observed even in the cheapest forms, but these are not subjected to critical tests, and any faults which are not apparent to the purchaser are allowed to pass, which is not the case in the highest grade, where the best is none too good; the result is, of course, that they are inferior, varying and unreliable, and while occasionally one may find an excellent lens among them, no reliance can be placed upon them. It has been computed that an error or variation from the spherical surfaces, for instance, so infinitesimally small that there are no mechanical means for determining it of $\frac{1}{100,000}$ of an inch, will have a noticeable and sometimes disastrous effect in the formation of an image. We all know, from the fact that we have read it often, of the utmost exactness with which a telescope objective must be made, and the claim is generally made that, because the image from the objective is magnified by the eyepiece, a greater perfection is required than in the photographic objective. I have found, however, that any lack of perfection which is noticeable by an eyepiece is as pronounced in the camera, and I therefore claim and make this emphatic, that a first-class photographic objective requires as much perfection as that in the telescope or microscope, and no work spent upon it to accomplish this result is lost.

To return to our objective, we will suppose that all the surfaces have been ground and polished. This in practice means considerable. The difficulty of doing the surfaces increases out of all proportion with the increase in size, as well as the danger of scratching. It is an ordinary event to scratch a surface during the process of grinding and polishing, and nothing uncommon to do so in the last stages of the latter, when the entire work must be repeated. No matter how good a surface may otherwise be, a scratch is inadmissible; not that it does any particular harm, but an optician who takes pride in his work cannot bear it, and the customer who has to pay for it will not accept it. After polishing, the lenses are put into a lathe one by one and centred—that is, the optical axis is found, which we know we have when on revolution of the spindle the two images which the surface gives are stationary. The edges are now ground down to the diameter of the cell in the mounting.

EDWARD BAUSCH.

(To be concluded.)

PHOTOGRAPHING THE NEBULÆ.

[Discussion on Mr. Common's lecture at the Camera Club given on page 56 in last week's issue.]

DISCUSSION.

THE CHAIRMAN (Mr. J. Traill Taylor) said he did not know whether this subject was one that would provoke discussion, but thought the wiser way would be for those who are somewhat backward on the subject of sidereal photography to put some questions to Mr. Common which, perhaps, he would kindly answer; and, by way of starting the ball, he would ask concerning the second slide shown on the screen—one which was taken at the instigation of Dr. Gill, at the Cape—whether that was done by an ordinary photographic lens or by a telescope? He observed that the stars were all slanting, as if the time had been an element; that is to say, the camera had been standing still while the heavenly bodies were moving, therefore he supposed it would have been scarcely an equatorial arrangement.

MR. COMMON: The reason of those stars being elongated in the direction you saw—and it required rather sharp eyes to see that—was this: The ordinary photographer's camera, taking a small plate with a lens of two-inch aperture and eleven-inch focus, was strapped on to a six-inch equatorial, and it was not stars that were followed, but the head of the comet; and the motion of the stars on the late represents the actual motion of a comet during about one hour.

THE CHAIRMAN: Thank you; that is very satisfactory. In the olden time used to point the camera to the heavens sometimes, and I recognised that effect in a very marked way. Means have to be taken to check the stars, to ensure that what we have got is not a speck of dust or dirt on the plate but really and truly a star. That can be done in the case of an equatorial arrangement by stopping the clockwork for a moment and duplicating it.

MR. COMMON: You have been anticipated there. Rutherford did that in 1864. He did that in a very remarkable picture he took of the Pleiades with an eleven-inch lens especially corrected for photography. He was one of those who found the limits of the collodion plate, because he never could get below the ninth magnitude. He then got his orientation. He allowed one star to troll along the bottom of the plate, and hence he got his photograph well marked.

THE CHAIRMAN: It is not a difficult matter to construct an equatorial stand of the lower type. I was a little sorry to hear Mr. Common say that photographing the moon was a waste of time. I used to be rather fond of that some years ago with a very humble appliance; but about twenty-six years ago, one year before I went into photographic journalistic harness in London, I constructed a stand, mounted a camera on it, and had a segment of a wheel and an Archimedian screw, and thus kept the moon tolerably sharp. I observe in some of Mr. Common's projections that the stars had very sensible discs. If we look at a star through a telescope it is simply a point. I was going to inquire how it comes that that point extended to such a very sensible disc as some of them, but I presume that it is by halation by the brightness of the star; the brilliancy is converted into space in fact. That is a consolation for photographers who employ lenses which are not so highly corrected for sidereal photographic apparatus as those costly instruments by which these admirable results have been produced. A landscape lens, for example, or any other kind of lens, even a telescope lens that is not corrected for photography, will give the stars definite discs by which they could be seen.

MR. COMMON: If it is badly focussed.

THE CHAIRMAN: But even if it is well focussed it might do the same, provided it is not corrected for photography, in the sense of the chemical and visual foci not being coincident; but I was going to ask, What is the cause of the disc, seeing in a high-class telescope there is no disc, and yet here, on the screen, we see the stars in various magnitudes?

MR. COMMON: I can only say it is only one of those dispensations of Providence which get us out of great difficulties, for if you consider what would be the effect if we took a photograph and found that the stars were all the same magnitude it would be very puzzling. It is a most interesting point, and I look to photographers to explain it. As you say, the image of a star in a good telescope is a point, and the question of a small telescope, which you alluded to on my interruption of your remarks, that it would show still a point—good focussing in that case means finding the focus by ascertaining the difference between the visual and chemical foci and using the actinic focus, which is the correct focus for work. But there is a remarkable thing under the production of stellar images, and it is that they vary in area in the same way as we have marked them in magnitude, and if you take the area of a star of the first magnitude and the area of a star of the tenth magnitude on the plate you will find they will vary in just the proper proportion of two and a half times the difference in magnitude. It is a most remarkable thing. I was careful enough to compare the photographic magnitude with the actual diameter of the discs on Henri's plates, and it came out in that way; and it is one of those remarkable dispensations of Providence which enable us to get out of a great difficulty, for it would be an enormous difficulty if we had to locate and specify which particular star was the first magnitude and which was the sixteenth. On the Henri plate it is in a very remarkable way that the image encroaches. They, for the purpose of identification, made them in little triplets; they exposed them one hour and got it on a triangle of five seconds. The very large ones still hold a very circular shape, as if they had been struck with a centre that was laid on the corner of the triangle. It looked as if vibration of the molecules went out just in relation to the time in which the plate was exposed; but, as I said before, it is to photographers I should look for an explanation of that very remarkable thing.

THE CHAIRMAN: Then I say it is simply lateral halation due to the bright spot being received on a diaphanous surface.

MR. COMMON: That is to say, in proportion to the brightness of that light so is the expansion?

THE CHAIRMAN: That is so. As I say, it is the conversion of brilliance into magnitude.

MR. LYONEL CLARK: I should like Mr. Common to tell us in what way we as photographers can help with our usual tools. We have not these marvellous five-foot reflectors or refractors, but is there any way by which we can with ordinary cameras help towards resolving this problem of the nebulae? There is a very interesting example in the photograph we have here of 31 M. When that nova appeared you could not be sure in any fixed observatory of getting a fine day; but if we made every amateur photographer on the globe capable of taking it, it would have been practicable to get a very large series of the nova as it appeared—the gradual way in which it increased in density. I saw it with an eight-inch refractor, but it was not fitted for photographing; but if it was possible for us to act in that way perhaps Mr. Common will tell us what we could do with the ordinary implements which an amateur photographer has at his command. With respect to the use of plates, I have not

heard Mr. Common make any remarks that the orthochromatic plates have been used. I think a great deal must depend upon the astronomer himself what colour he gives a star. I think it must depend a great deal upon his ability to estimate colours. There is a nova in Cassiopeia particularly—a blood-red star which happened to be described, and the right ascension and the declination was given in *The Observatory*. I think that star would have been absolutely insensitive to any ordinary plate, but with the orthochromatic plate, as Captain Abney says, we can do it—it would be able to be obtained. Gemini is rich in ruby stars. Granulation must undoubtedly come out in the using of such plates, for if we use a very rapid plate, then the granules of the emulsion are larger than in a slow plate. In very rapid emulsion you can see the emulsion standing up in a coarse grain altogether. Therefore it is somewhat a drawback in those plates that in order to get smaller grains we get a longer length in the telescope. Whenever I have worked with orthochromatic plates I have found they are so much more granular than any ordinary plate, and I think the fineness of the image is inversely as the speed of the plate. Of course a series of exposures made of any nova would be most useful for determining the luminosity; it, no doubt, would be the chemical value, but a chemical measurement is much more trustworthy than any optical one, and I fancy measuring the stars will not be obtained by the ordinary wedge photometer, but will be based upon some chemical apparatus. Captain Abney, in his experiments, gave a certain quantity of squares exposed to different lights for an equal period of time, and in that way he got them on the actual plate he was using; that is to say, he got a perfect scale alongside by which he could compare the deposit exactly with the actinic value of the plate. Another thing is the use of the eyepiece. Were these photographs by M. Gothard taken with the eyepiece?

MR. COMMON: No.

MR. CLARK: They were not taken direct?

MR. COMMON: Yes.

MR. CLARK: Is it an advantage to use the eyepiece, or is it better to take it on the film and enlarge from the film? I think this is an important point. If it is practicable to use the eyepiece I think that would be rather a simple way of correcting any ordinary astronomical telescope which is corrected for actinic or visible rays.

MR. COMMON: It will not alter the image originally formed by the telescope. An enlarging apparatus that is correct itself, and which you may consider perfect, will not make an image imperfectly formed into a perfect one. Touching that point of applying the lens, Mr. Christie did apply a corrector to the equatorial, and he found very excellent results from a Barlow lens lengthening the focus of the original and tending to bring the otherwise divergent rays to the one common point.

MR. CLARK: I believe that is the way the Lick telescope is corrected?

MR. COMMON: No, it is not. The telescope has a flint glass of thirty inches aperture placed in front of the object glass which shortens the focus by ten feet.

MR. CLARK: Would it not be possible to use a process described by the Chairman? In the old days of photography the lens never was corrected for any other than the visual focus, and an arrangement was made by which he placed in the axis a simple lens of the value of the difference between the visual and actinic foci with which he made the visual focus, and when it was taken away he got the actinic focus exactly right; but we are working with a flint focus. We can use for correcting it a lens of very much smaller aperture. We can correct it with the stop on any one of the more brilliant stars at very much less expense than the whole lens. Two such lenses with another two-foot lens would be very expensive, but by using a corrector for focussing, and by removing it for the exposure, we get all the advantage at a very much less cost during exposure. That is a point I wish to ask, and whether Mr. Common thinks it is possible that photographers in any way can help astronomers?

MR. COMMON: Touching the correction of the two-foot lens by a six-inch diameter placed in the converging cone of rays, it would have two effects: In the first place, it would affect the field very considerably; the central pencils would be right, the marginal pencils would be largely spread. It is no use using the two-foot lens when you can get a two-foot speculum. With regard to the use of orthochromatic plates, it is necessary to consider your plates. If you are going to make comparisons between photographs taken at one time and those taken at another you must be careful to have the plates sensitive to the same part of the spectrum, otherwise you will get various difficulties. The whole thing is quite in its infancy yet, and all these questions are questions that want solving. They will be discussed as our knowledge increases by experiments, for that is the only way I know of to work safely and properly. As to how photographers can help, there are several things I should like very much to know and photographers can tell me. I should like to know how to get on the plate the greatest amount of faint detail. That is a question which depends largely upon the developer as well as upon the plate. You will get with one developer a picture that would not show so much fine detail as with another developer. That is one point where the photographer can come to the assistance of the nebula photographer very well indeed, and my impression of that sort I shall be very grateful for. How to get a plan to show the effect of the faintest light upon the surface; to get, in fact, the greatest amount of faint detail. A lot of these nebulae stretch away for dozens against the sky; in fact, I am not sure that the whole sky is not one mass of nebulae. I would make a remark about the plates. In 1890 I was

examining the Pleiades with the telescope, and I made a note in the *Monthly Notices* of the Astronomical Society, and I was met with the remark that I had been using the telescope with an inferior aperture. No one saw those patches until Mr. Roberts and the brothers Heuri photographed them, and, by Jove! there they were. Going back to that point, I want to have one hit back and get something out of you as to this point, if I might.

THE CHAIRMAN: I remember, at the Birmingham Photographic Convention last July, when I prevailed upon the Rev. S. J. Perry to give us an address on celestial photography, he dealt largely with that question, and he said every photographer could assist by taking a small portion of the heavens and photographing it with ordinary photographic appliances and examining the results. I think that is what Mr. Clarke was referring to.

MR. CLARK: Yes.

MR. COMMON: If there is any willingness on the part of photographers to help us, they must help us in the way in which we want help.

THE CHAIRMAN: Mr. Perry, as an inducement, said there was no knowing what a number of comets one might catch!

MR. CLARK: Does Mr. Common back his plates for halation?

MR. COMMON: No, never. You are liable in certain weather, and I think the fog has something to do with it to get a ring round some of the brighter stars. I took a photograph on Sunday night with an hour's exposure, and one of the brightest stars in the margin of the plate had a bright, defined ring, and Colonel Tuxman has the same thing. It is not a thing you can always get.

Colonel TUXMAN: You can always get it with long exposure. The diameter of the ring is often four times the thickness of the plate.

THE CHAIRMAN: That is halation.

MR. CLARK: That is curable by backing or by staining the film.

Colonel TUXMAN: You cannot prolong the exposure enough if you colour it.

A MEMBER: On the contrary, you increase the exposure.

MR. COMMON: All these questions are burning questions which require elucidation. I have been confining my remarks to one branch of a very large subject. The subject of astronomical photography is an extremely large one. It is only in the last decade that anything has been done. The number of men who worked on the nebulae you could count upon your fingers at one time, while for the number of men who could work on them is great.

A MEMBER: But it is a very doubtful point whether orthochromatizing does not affect the light.

MR. CLARK: It will not so much affect the faint light, but it will affect the bright light.

MR. COMMON: I spoke to Captain Abney years ago about this. I believe you could get a great deal more detail of the nebulae. Blue nebulae are all right and will work on the present plate, but I think if we can get orthochromatic plates they will work in the red end and we might get some surprising results.

MR. CLARK: It is almost within the last fortnight that any success has been obtained in photographing well down in the red.

MR. COMMON: Apart from this question of what may be done, there is at the present moment a great deal that is possible to be done which is not being done. These things are very interesting in themselves, and will no doubt assist us further on, but there is a tremendous lot now which ought to be done in concerted action in photographing nebulae as well as stars. That is the point I want to bring before you to-night. Other things, of course, will follow. We cannot neglect any advantage that will come through a greater fineness of the plate or a greater sensitiveness; but with the present appliances, particularly after the work of M. Gothard with such a small instrument, there is a possibility of doing an enormous amount of work with the present instruments and the present plates.

A MEMBER: With regard to the fineness of the deposit on the plates, it has been said this evening that the more rapid the plate the more coarse the deposit. That is so as a general rule, but that is not always absolutely the case. I have been comparing some bromide paper and Chapman's gelatino plates. The sensitiveness is about the same—perhaps Chapman's plates are less sensitive. The bromide paper produces quite a coarse grain deposit, but gelatine and albumen plates—how they are made I do not know—are about the same rapidity and have a very much finer deposit. If it is true, as the advertisements say, that they do contain albumen, it is possible in using these plates that we may use finer plates. You must be struck with the remarkable fineness of these plates, and I have not been able to see any grain at all with even a strong magnifier.

THE CHAIRMAN: It is a characteristic of albumen plates that if properly prepared they give a stain. You can apply a power of, say, a quarter of an inch microscopic power to them without showing sensible granulations.

MR. COMMON: This would be invaluable on such an object as the moon because you have so much light. It is difficult to get a sufficiently short exposure with the present plates, so that if you had a plate one-half as sensitive, or one-tenth as sensitive if you had the means of getting a finer deposit, you have the means of getting a better picture. I do not know the most sensitive plate to use. If any one will tell me of a sensitive plate I shall be glad.

MR. CLARK: Cramer's "Seed" plates.

MR. COMMON: I have tried the Seed plates, and they are not a bit more sensitive than Paget's plates, and in other respects with regard to deposit I do not see that they are a bit better. I was so decided about it that I ordered

a few dozen plates that I wanted, because I like to have all plates made in one batch, and I know they are all the same, and I begin to learn all the peculiarities of them before the finish of the batch. I have ordered those plates in preference to getting more of the Seed plates.

Mr. CLARK: But do not you find that with rapidity you get a much coarser deposit on the silver?

Mr. COMMON: No; I am satisfied so far as they have gone, but I should like to get them finer.

A MEMBER: Have you tried hydroquinone?

Mr. COMMON: I used it when it was twelve shillings an ounce; now it is two shillings. Instead of using hydroquinone I put in as much pyro as would stand on half a crown, and I put an ounce and a half of water and two ounces of potash solution, and I got beautiful results.

A MEMBER: One of the greatest necessities of the case is to keep the pyro down and with no bromide whatever.

Mr. COMMON: I found I used too much pyro. Everybody has found what I have found myself, that it is of infinitely greater importance to get a middling developer and know its practice than to be butterfly about from one formula to another. I have always got the best results by sticking to Paget's plates and sticking to the developer as long as I could.

The CHAIRMAN: I think we should tender to Mr. Common our thanks most cordially and heartily for his eloquent discourse and for permitting us to see that which to so many of us is invisible. (Applause.)

The proceedings then terminated.

COLLODIO-BROMIDE EMULSION.*

My experience with the carbonate of ammonia developer was rather unsatisfactory. I mixed the solution according to Mr. Brooks's directions: it had a strong odour of ammonia, which I presumed was the alkali intended to bring out the picture, but somehow it failed, and it was only by great patience and perseverance that I succeeded at all. Mixing it as directed, and pouring on and off the plate, it took at least five minutes before the faint show of an image appeared, and by constantly working over the plate I managed to secure a slide in about twenty minutes, somewhat over dense in the shadows, which I regarded was due to too slow development.

I mixed up half an ounce of dried carbonate of soda—not the ordinary crystals—in ten ounces of water, and applied two or three drops to the same developer, when used on another plate, and to my gratification the image appeared rapidly, and acquired the requisite density and brilliancy in the time I thought it ought to. Remembering that I used to employ the soda on Mr. Newton's plates long ago, and meeting Dr. Higgins, who also advised it, I have ascertained that it is much better than ammonia, and puts the relation of exposure to developer on a solid basis. We have no fickle alkali like ammonia, but a certain fixed alkali, which may be relied upon to act as you expect it should every time. Mr. Newton advises using the pyro dry; I obtain just the same results in slide making by using it preserved in solution with sulphurous acid and sulphite of soda. It prevents the developer from getting muddy, which it is otherwise sure to do if you are compelled to prolong the development. I believe the only person suggesting the use of hydroquinone on these plates is Captain Abney in his work on *Photography with Emulsions*. I have tried it, and think, if anything, it works quicker than pyro, and produces equally as good results.

Therefore, for Brooks's emulsion I can recommend the following developers:—

Stock Solution, No. 1.

Carbonate sodium (dried)	230 grains.
Sodium acetate	120 "
Potassium bromide	120 "
Water	10 ounces.

No. 2.

Sulphurous acid and sulphite soda, pyro solution, after my formula based on the strength of forty-eight grains of pyro to the ounce, or any other pyro solution based on the same strength.

To develop a slightly over-exposed plate, add twenty minims of the pyro No. 2 solution (and the same amount also of No. 1), then fill the graduate with water until the whole measures half an ounce.

You thus have a dilute developer to begin with. The image will appear in a few seconds (probably ten) after the developer is applied, and will be finished in about a minute, or perhaps three. Then the image is examined by transmitted light, and when the desired density is reached the developer is poured off and the plate washed under a gentle stream of water for a few seconds, just enough to clear it of the developer. If the water runs too strong it is apt to split the film and carry it off the plate.

Then comes the fixing in less than half a minute with the cyanide, which is most rapid, leaving the high lights beautifully clear, and the dense portions exactly as you saw them before fixing. The cyanide is

* Continued from page 41.

quickly washed out under the tap or by soaking the plate in water. In a few minutes the plate may be dried by heat over a lamp or near a stove, then varnished, and it is ready to mount. Here there are two important advantages over gelatine, the non-over-fixing out of the dark portions and the rapid drying. If the developer works slow, and the image appears to be slightly under exposed, simply add a few drops at a time, at short intervals, of the No. 1 solution until the details appear sufficiently out.

I rather prefer the hydroquinone to the pyro, because it keeps better, and you can use the same developer over again. It appears to give the plate equally as good a colour as pyro.

I mix a solution as follows:—

Hydroquinone, chemically pure	15 grains.
Sodium sulphite, chemically pure	40 "
Distilled water	1 ounce.

Put one and a half drachms of the above into the graduate, add twenty minims of the No. 1 or soda solution, and fill with water until it measures four drachms, then apply to the plate.

This process is especially useful in making slides from negatives having thin skies, and when it is found that the sky of a slide is veiled or fogged, it may be readily removed by the use of an alcoholic solution of iodine.

Mr. Brooks states that the solution should be prepared as follows:—

Iodine	20 grains.
Alcohol	1 ounce.

Drop a few drops of the above into an ounce of water; if the solution should appear cloudy a little more water added will clear it, pour on and off the plate from a developing measure for a minute or so, and if one place seems more fogged than another pour on and off that part, the high lights will assume an opalescent appearance. When this has taken place wash well under the tap and again pour over the cyanide solution. The image will then clear up and the fog will be removed from the high lights. This manipulation can be repeated until the desired effect is obtained.

If properly exposed and developed the slide should have a brown tone by transmitted light. Mr. Dunsterville gives the following for toning and strengthening, which I have not had time to try:—

To tone the transparency take—

Platinum tetra-chloride	1 grain.
Nitric acid	1 minim.
Water	4 ounces.

And immerse the plate. Watch carefully, as the toning proceeds very rapidly. As soon as the wished-for colour is produced, take the plate out at once and wash well and quickly. Should the toning have gone too far, the warm colour may be restored by flowing again over the plate the alkaline developing solution and the toning done over again more carefully. Should the picture appear too thin after toning it may easily be intensified to any degree by the following solution:—

Pyrogallie acid	30 grains.
Citric acid	30 "
Alum	30 "
Distilled water	15 ounces.

To each drachm of this add two or three drops of a twenty-grain solution of silver nitrate.

Should the picture appear too dense after toning, it may be reduced by flowing again over it the cyanide fixing solution.

I may remark, further, that these plates can be developed with a weak ferrous oxalate developer, restrained with bromide of potassium, as easily as gelatine plates. I have been thus explicit as regards details in order that any amateur wishing to make these beautiful pictures may have a practical guide that is reliable, and I trust some of our members will try working the process.

It is well known that the perfection of the collodio-bromide process in this country was largely due to the exhaustive experiments carried on by Mr. Henry J. Newton, and I have deemed it but just to him and all American workers to include in this paper his formula for an unwashed collodio-bromide emulsion as now given to me by Mr. O. G. Mason, of Bellevue Hospital, who, as some of you may know, is still using Mr. Newton's formula. The collodion is prepared as follows:—

Alcohol	} Equal quantities.
Ether	

Pyroxyline (gun-cotton) six grains to each ounce of alcohol and ether used, compounded as follows:—

Put the alcohol in a bottle of sufficient capacity, then add to each ounce sixteen grains of bromide of cadmium, then add to each ounce twelve grains pyroxyline, and, lastly, add as much pure concentrated sulphuric ether as alcohol used. Let the collodion thus made stand several days to ripen and settle.

To silver the emulsion, prepare for each ounce twelve and a half grains nitrate of silver crystals by pulverising in a mortar, put it in a flask or

bottle, and add for each two grains of silver one drop of water, and apply gentle heat, preferably over a water bath, until dissolved.

Then add to this dissolved silver four drops nitric acid for each ounce of emulsion to be made, and while the mixture is yet warm, not over 100° Fahr., add it to the proper amount of bromised collodion, as previously given. Let the whole stand six hours, then add to each ounce of bromised and silvered emulsion one grain of tannic acid.

At the expiration of six hours for clear brilliant work (or twelve to eighteen hours for a more sensitive plate), after adding the tannic acid, add for each ounce of emulsion three grains of finely pulverised chloride of calcium, and shake the mixture until the calcium is dissolved.

The emulsion improves by age and frequent shaking. He says nothing about the developer, but I presume he employs the soda and pyro developer always recommended by Mr. Newton.

(To be continued.)

F. C. BRACH.

SUN PICTURES.

THE second of the free popular lectures to be delivered this session at the Working Men's College, Great Ormond-street, was given recently to a large audience by Professor B. Thompson Lowne, F.R.C.S., his subject being "Sun Pictures." Professor Gringon presided, and briefly introduced the lecturer. Professor Lowne, in his opening remarks, said that one of the first exhibitions which he saw when he was a little boy was a camera obscura—a very beautiful and wonderful invention. He supposed the fact that a lens made a picture must have been known for centuries, but this particular kind was invented two centuries ago by an Italian physician. This was one kind of sun picture, but there was another kind which they saw in every photographer's window, and the latter had grown out of the former. How that art had grown up since the early days of the present reign! It had grown up into something which was most elaborate and most wonderful, and he was going to try and explain to them how it had grown up, and the principle upon which these pictures were made. In his other lecture he would tell them something about a much more wonderful phenomenon, which was much older than photography, and much older even than the human race, which had grown and grown with the human race, and had attained a marvellous perfection, and the time would come when it would attain to a more marvellous perfection still. Within the last thirty or thirty-five years he had travelled all over the world and seen everything which was worth seeing, yet, with the exception of one or two short voyages, he had done it all within the four walls of his own study. He had seen mountains and most wonderful plants and animals, and when by any chance he had come upon any of these things he had seen, by means of what he called brain pictures, he had found that they were the very identical things which he had expected to see. So far as he could judge from the experience of his life, and from having been able to compare brain pictures which he had seen with the realities which had inspired them, he had found that they were as like as two photographs, and in fact there was something in the production of the brain picture which was very like the production of a photograph. The professor then proceeded to explain, by means of familiar parallels, the action of the lens, and through it the images formed in the camera obscura. It was founded on the principle that a lens brought the light which came from a point back to a point. He then went on to trace the development of photography. In the dark ages there were men who were seeking to learn secrets, not for the sake of knowing them, but for the purpose of finding the elixir of life, and with it the way to make gold. Amongst other discoveries they found that silver with common salt, under certain conditions, gave rise to a new substance, which they called horn silver, the yellowish compound which was known now as chloride of silver, and they discovered also that this substance, when exposed to the sunlight, turned black. They did not trouble themselves much about this discovery, but in 1802 Mr. Wedgwood and Sir Humphrey Davy set themselves to work to find whether pictures could not be made with horn silver upon porcelain or some other suitable substance. They covered porcelain with lunar caustic and exposed it to the camera obscura, or put a leaf or flower on it and exposed it to the sunlight. In a short time they got a picture, all the parts of the prepared porcelain not covered turning black, and those partially shaded becoming dark. But they could get no further with the process, for they found no means of preserving the picture, which faded directly it was exposed to the light. Nothing came of the discovery till 1814 or 1815, when M. Niépce made experiments another way, and got a permanent light picture, but even he had to expose his photographic plates for twenty-four to forty-eight hours before he got any result. M. Daguerre, after twenty-five years' work, in 1839, was able to announce to the world that he had made a permanent photographic picture. But still it took from fourteen to twenty minutes' exposure before a picture could be obtained. He discovered what modern photographers called "development," which was the most beautiful process in photography. He got very beautiful pictures, and the only question was how to shorten the time taken in producing them. Mr. Fox Talbot, an English gentleman, was labouring at the same time in another direction, and found a means of taking pictures on prepared paper, for they had hitherto been only taken on metal. Since these days photography had taken

enormous strides, until, at the present time, an express train, a flying bird, a racehorse at full speed, could be transferred to paper—the operation taking the minutest fraction of a second.

DUTCH RIVER SCENERY FOR THE CAMERA.

IN TWO PARTS.—PART I.

FOR those who have abundant leisure for the time being, and who feel reduced pleasure in careering round Europe with the velocity of a sky-rocket, there is no more lazy, pleasant, sleepy way of traversing portions of the Continent than by its lake and river boats. Under an upper deck awning, screening the tourist from the sun, the happy hours may be dreamed away, or photographs taken at comfortable leisure with endless changes of real scenery obligingly placing themselves in front of the lens. The developing room down below, or in one of the little deck cabins lent by its obliging official occupant for the occasion, is kind enough to accompany the tourist on his travels at the expenditure of no exertion on his part; on long river journeys the bedroom or bunk travels with the developing room, so also does a restaurant. One of the longest journeys of this kind, with a starting-point within easy distance of London, is first up what may be called "the unvisited Rhine," and next, in the same boat, up what might be called "the over-visited Rhine," that is to say, the particular German portion so well known to tourists.

Of the "unvisited Rhine" it is my mission now to speak, for I traversed it by boat partly out of laziness and partly out of curiosity about sixteen months ago. The Rhine, which the German worships as a Hindoo worships the Ganges, and which is the subject of Teutonic songs and legends innumerable, rises in the mountains of Switzerland, and acquires some volume after leaving the Boden See, called by us the Lake of Constance. This lake acts as a natural reservoir, and as the Swiss glaciers in its vicinity melt in the summer's sun and pour their waters into the lake, so does the river rise in far-off Germany and Holland; hence, curiously enough, there is most water in the Rhine in the summer, whilst in the late autumn, when there may be plenty of rain about, the river is at its lowest. Sometimes the water will rise or fall considerably in a few hours owing to meteorological pranks in the Swiss mountains, to the discomposure of the stolid people who live and work far away on the lower reaches of the river. Near Basel or Bâle are the great falls of Schaffhausen, after which the Rhine winds for many scores of miles through pretty country—sometimes flat, sometimes hilly—to Mannheim, where its passenger steam navigation now practically begins. At one time small steamboats found their way the whole of the long journey thence to Bâle, but shifting sand and mud banks of late years have proved more than a match for the steamboats on the higher reaches of the river. Coming down the Rhine from Mannheim the more celebrated part of the river, visited for the beauty of its scenery, begins at Bingen and ends near Bonn. English passengers traversing this best part of the Rhine usually have boat tickets available between Cologne and Mayence. After leaving Cologne on the downward river journey, Düsseldorf, hallowed by the names of Liesegang and Hubert, is the next large place reached; lower down the Dutch frontier is crossed, and the river winds its way all across Holland to Rotterdam, before reaching which place it throws out many arms, so that it is somewhat a matter of choice to say which of them is the Rhine and which is not.

The passenger who leaves Liverpool-street, London, at eight in the evening, finds himself on board the boat at Harwich a little after nine o'clock, and at Rotterdam at about seven or eight o'clock the next morning. On landing he may tell a cabman to take him to the boat of the "Niederlandische Dampschiffe-Rhederei," or should this be too much exertion, tell him "to the Rhine boat of the Dutch Company." (Plenty of cabmen, common workmen, and all kinds of people about Rotterdam speak English.) Or he may ask to be driven to the Rhine boat of the Cologne and Düsseldorf Company, for two companies ply for passengers between Rotterdam and Mannheim. They do not run their steamers in official connexion with the Harwich boats, but usually start at times when passengers thereby have a good chance of catching them. They start from the same side of the river as the Harwich boats, but a mile or thereabouts higher up, the intervening bridges, and the irregular times of opening them, making it inconvenient for the Rhine boats to come down to the same pier.

Suppose the tourist photographer to have boarded one of the boats of the Dutch Company, to go slowly as far up the Rhine as he can against stream, here is the journey he has before him—I quote from an old timetable, at present I believe the boats start at a later hour:—Rotterdam, 7 a.m.; Nymwegen, 3.30 p.m.; Emmerich, 2 a.m.; Wesel, 5 a.m. (one day and night); Düsseldorf, 12 midday; Cologne, arrive, 5 p.m.; Cologne, depart, 10.30 p.m.; Bonn, 1.30 a.m.; Coblenz, 7.45 a.m. (two days and two nights); Bingen, 1.15 p.m.; Biebrich, 3.30 p.m.; Mayence, arrive, 4 p.m.; Mayence, depart, 3 a.m.; Mannheim, 8.30 a.m. (three days and three nights from Rotterdam). The return voyage with, instead of against, the stream is quicker. I think a line of passenger steamers direct from London runs in connexion with the Rhine boats of the Dutch Company. The way to ascertain is to write to the Company at Rotterdam, and ask for the information, together with a time-bill, list of fares, and tariff for sleeping accommodation and "restauration." All these

will be found to be astonishingly moderate for first-class or other accommodation, and doubtless it will be a surprise to many a photographer to discover how easily and cheaply he can thus spend, if but a week, in penetrating to the very centre of Europe and back again, carrying with him his bedroom, sleeping room, restaurant, and steward who speaks English, for language is an impediment to many photographers in the matter of foreign excursions. If my memory is not at fault, the Rhine boat tickets for long distances allow the bearer to break his journey wherever he pleases along the route, so that he need not sleep on board should he feel otherwise disposed.

In the times stated in the preceding sentence a portion of the more picturesque part of the Rhine, namely, that between Bonn and Coblenz, is not altogether passed in daylight; the finest scenery of all lies higher up, between Coblenz and Bingen, and all the morning is occupied in traversing this length. Coblenz is an interesting place, strongly fortified, at the mouth of the Moselle; opposite it is the great fortress of Ehrenbreitstein; all around the scenery is magnificent. The Germans do not seem to make so much fuss as do the French about photographing near fortifications from points of view which may be described as thronged places of public resort; those photographers who get into trouble seem, from the published accounts, to be, for the most part, persons who have selected special and out-of-the-way points of view, so may be supposed to have almost intended to invite suspicion. Mr. William England has lantern views of Ehrenbreitstein fortifications as seen from Coblenz, so which cannot be supposed to contain anything of a private nature; had the same class of photograph been taken in France he would probably have had rough treatment. From Coblenz those with leisure may make a day's excursion up the Moselle, along which river steamboats run of about the size of the penny boats on the Thames, but not such dismal, poverty-stricken structures. How comes it that the Thames has probably the worst river steamboat service in Europe? If some decent, comfortable boats were substituted, like those on the Seine, river travelling in London might become as popular as it is in Paris, where the boats, with their comfortable and roomy saloons, stuffed seats, electric lights, and so on, are usually well filled. The running of a Paris steamer on the Thames would make a sensation in London.

The time-tables of the Rhine boats give mostly but the principle stopping places: the full list of all stopping places would be a long one; but at most of the smaller places in Holland the steamboat merely pulls up for a minute or two in the middle of the river, whilst passengers are taken on and off in a small boat at a trifling cost.

In giving this general description of the Rhine and its long-distance passenger services, the space at command has been exhausted before reaching details about what can be photographed in the way of river scenery in that curious country, Holland, inhabited by curious people, so that matter is postponed until the second part of this article is reached.

The headquarters of the larger and richer passenger steamboat company, the Cologne and Dusseldorf Rhine Steamboat Company, are in Dusseldorf, whence information can be obtained on application. This is a newer company than the Dutch one, the boats of which latter have been running for a generation or more. Some engineering literary duties late in 1887 caused me to go into the whole subject of the history of the steam navigation of the Rhine.

The photographer who wants quiet and rest had better not make this long water journey in the fashionable autumn season, when the boats between Cologne and Mayence are crowded by all the world and his wife. A fortnight after the season is over, he and a half a dozen other passengers may possibly have all the saloon and half the best part of the boat to themselves. Neither should they traverse the lower reaches of the Rhine in wet or foggy weather, for then the flat country and everything else will be depressing in the extreme; but given bright sparkling weather, this is one of the liveliest trips obtainable near London when judged from a photographic point of view, as I hope to show hereafter.

W. H. HARRISON.

PATENT COMPLETED.

A NEW AND COMBINED APPARATUS OR DESK FOR RETOUCHING PHOTOGRAPHS. No. 3352. EDMUND JOHN PASSINGHAM, 14, Tyttel-street, Bradford, Yorkshire. *March 5, 1888.*

THIS invention has for its object the combination of certain parts in such a manner, so as to be enabled to construct an apparatus capable of being packed into little space, and which, when fully opened, is capable of receiving and holding photographic negatives in such a position that the same may be examined and rectified of any defects, and when folded into another position the same is converted into a desk suitable for examining and rectifying positive photographs.

I form the apparatus by hinging together four boards or plates, the base-board or plate being provided with supports by which the adjoining board or plate hinged thereto may be elevated and held at varying angles of inclination; and to the last-named board or plate is attached an adjustable mirror.

To the mirror supporting board or plate is hinged another for holding the negatives, and in which is inserted a piece of ground or semi-transparent glass, over which the negative is held by a suitable clamp, the mirror being in such position that the light is reflected through the before-mentioned glass and negative covering the same.

A cover is hinged to the last-named board or plate, and the sides connected by opaque flexible material, for excluding some of the light in the room falling on the negative, the cover being held in position by a support attached thereto.

On partly folding the apparatus the same is converted into a desk, the inclination of the same being adjustable and held by one of the before-mentioned supports.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday night, last week, at the ordinary meeting of the above Association, Mr. W. E. Debenham presided.

Mr. A. L. HENDERSON said that in some experiments which he and a Brighton photographer had made, a rather explosive sample of gun cotton was dissolved in ether and alcohol, then mixed with chlorate of potash and magnesium powder, and dried; small portions of this could be exploded when desired to give a flash light. Amylic alcohol would dissolve celluloid.

Mr. A. HADDON remarked that the most explosive descriptions of gun cotton were absolutely insoluble in alcohol and ether.

Mr. W. H. HARRISON stated that the British Government authorities would not give a license for the manufacture of any explosives containing chlorate of potash; such compounds were highly dangerous; they were liable to explode under the influence of a glancing blow as well as from other causes, although a few of them might be used safely for a time.

Mr. HENDERSON knew of a case in which the admixture of chlorate of potash in an explosive had been permitted by the Government.

Mr. J. J. BRIGNSHAW exhibited a specimen of Bell's asbestos cloth, also some of the material from which it had been made.

The CHAIRMAN remarked that asbestos cloth had been known from times of high antiquity; the ancients used it sometimes to envelop bodies which were to be cremated.

Mr. BRIGNSHAW had heard that mummies had been wrapped in it.

Mr. EDGAR CLIFTON doubted it, as there was no object in so doing. An aged bitumen was found in mummies which made a useful pigment; perhaps that bitumen might be useful in the photo-zincographic process.

Mr. HADDON said that asbestos cloth was useful to put between glass chemical flasks and flames to moderate and more equally distribute the heat.

Mr. HARRISON stated that "asbestos" meant "the undefiled" or "the imperishable," and that the ancient Romans would clean raiment made of it by throwing such garments on the fire.

Mr. C. H. COOKE had some carbon tissue which when not quite dry had stuck to parts of a negative; how could he remove the stain?

Mr. A. COWAN recommended him to try caustic potash in weak solution.

Mr. LAWROD exhibited some bromide paper prints which had been cleanly and evenly developed by hydroquinone after he had developed four negatives in the same solution; he had cleared them with weak hydrochloric acid.

Mr. T. E. FRESHWATER asked the cause of certain spots on negatives on gelatine plates which had been sent him from India to obtain the information.

Mr. HENDERSON thought that they might be due to insufficient motion of the plate during development.

Mr. P. EVERETT thought that high temperature of development might have partly dissolved the gelatine.

The CHAIRMAN believed that high temperature would set up frilling before it produced spots.

Mr. HENDERSON suggested that the spots might be due to undissolved particles in a strong solution of alum.

A question was asked, "What is the best leather for camera bellows?"

Mr. EVERETT suggested Russian leather, as it was attacked neither by damp nor insects.

Mr. CLIFTON believed Morocco leather to be the best, where expense was not an object. As a matter of fact, he believed that sheepskin was the material actually used.

The CHAIRMAN called attention to some sunk mounts sent by Mr. Fallowell to the meeting for exhibition. He believed sinking to be best done after the prints had been rolled.

Mr. COOK thought that prints should never be rolled or glazed.

Mr. W. H. FRESTWICH said that rolling would not take out a plate mark.

Mr. T. KERR exhibited two negatives—one taken with a roller blind shutter next the plate, the other with the same roller blind shutter close to the back of the lens; the latter negative had received far more action from light than the former. He added that he had always argued that the proper place for a roller blind shutter was at the back of the lens.

Mr. COWAN remarked that if Mr. Kerr thought the matter out he would find that he had considerably lengthened the exposure by placing the same shutter with the same large aperture close to the back of the lens.

The discussion of the subject of roller blind shutters was adjourned.

The question was asked, "What is the formula for making shellac varnish for glazing collotypes?"

The CHAIRMAN thought that borax dissolved in ammonia was used; to this Albert used to add a small proportion of alcohol. He did not remember the proportions used.

Mr. EVERETT asked if there were any advantage in using a lens of larger diameter, supposing it to be stopped down to the same extent as the aperture used with a lens of smaller diameter.

The CHAIRMAN replied that under certain conditions the larger lens would give more illumination at the corners of the pictures.

CAMERA CLUB.

On Thursday, January 24, Mr. W. MARRIOTT, Assistant Secretary of the Royal Meteorological Society, read a paper on the *Application of Photography to Meteorology*. Mr. Francis Cobb occupied the chair and introduced the lecturer, who gave a most interesting account of the uses and application of photographic paper in securing automatic records of barometric and thermometric variations. He also described the processes adopted for measuring the movements of clouds, and drew attention to the subject of lightning photography, pointing out the assistance in this matter which photographers could afford to the work of the Royal Meteorological Society.

Some interesting apparatus and a large number of photographs, barograms, and thermograms, were on exhibition in the rooms. Some discussion followed, in which Messrs. Elder, Whipple, Symonds, Ferrers, Lionel Clark, Stroh, Captain Wilson Barker, and Dr. Marcet took part.

The subject on Thursday, February 7, will be *Entargy*, when Mr. J. E. Austin will read a paper. Mr. Austin will illustrate his subject with some enlargements on Alpha paper, which will be shown in the rooms.

WEST LONDON PHOTOGRAPHIC SOCIETY.

At the meeting on Friday, the 25th instant, Mr. William England, the President, in the chair, Mr. John A. Rogers gave an account of a tour with the camera in North Wales, illustrated by the exhibition of upwards of fifty slides produced by himself from his own negatives.

At the conclusion of the descriptive portion of his paper the lecturer said that, as he was addressing an audience of photographers some of whom might not have had much experience in touring with a camera, a brief reference to his own experiences might prove instructive. In regard to the size of the camera, he was of opinion, taking comfort and convenience into consideration, that a half-plate camera was the largest size that could be carried for a whole day in a mountainous locality by a person of ordinary physique; and, personally, he preferred a 5 x 4, or even a quarter plate. The small pictures were large enough for presentation or for mounting in an album, and, with the exercise of ordinary care, excellent enlargements of any desired dimensions could easily be produced. Further, the small negatives afforded an easy means of making transparencies for the lantern by contact printing, although better results were obtained by reduction in the camera.

On Friday, February 8, Mr. Wallace Bonetto will read a paper on *Lighting and Focusing*, and Mr. J. Desiré England will give a demonstration of the method of using the flash light for portraiture. Visitors are invited.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

The annual dinner of the above Club went off with great éclat at Beale's Restaurant on the 21st ultimo. Each diner had a 5 x 4 photographic menu, one of the *entremets* being *Feasting & its Photography*. After the toast a smoking concert was held, at which Messrs. Saville, Beckett, Hiscock, Pither, Crutts, Humphries, Stewart, and Rayment, assisted.

On Monday evening, January 23, the Club held a meeting in the Iron Room, Strand Green, when the subject for discussion was *Cameras*.

Mr. V. W. Davies Broughton, of Hatton Garden, exhibited two cameras of his own make, of good workmanship and design.

Mr. William Beck, jun. (of Messrs. R. & J. Beck, Cornhill), exhibited one of

their hand cameras, which embodied many improvements, some of the specimens of its work shown being especially good.

Mr. Martin exhibited some prints from negatives taken with the flash light. The next meeting will be on Monday, February 11.

MANCHESTER PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held January 10, 1889,—Mr. J. S. Pollitt in the chair.

The following gentlemen were elected members:—Messrs. R. J. Kerr, A. L. Bostock, T. Grosse, T. Broadbent, T. Beeston, F. Spencer, Rev. C. P. Smith, and S. Tiller.

Mr. JOHN SCHOFIELD demonstrated the fact that a gelatino-bromide negative may be developed without the aid of a dark room, viz., by a developing solution coloured by a dye that is very soluble in water; and, though staining the film before and after development, the stain can be washed out entirely during the ordinary washing after fixing. From a number of experiments Mr. Schofield had made he concluded eosine was the best. Mr. Schofield said: I first take sufficient water to cover the plate about one-quarter deep, to which add enough eosine solution to give a deep ruby, place the dish containing this coloured water under a cloth, and turn the gaslight down, or select a place where the daylight is much reduced, but sufficient to see; having placed the dark slide along with the developing dish, open it under the cloth and pass the plate into the coloured water for about two minutes; now put into the developing dish the pyro, ammonia, and bromide in the usual way. The negative now can be uncovered and the coloured water mixed with the developing salt in the cup, and again returned to the plate, and development proceeded with in the usual way. The plate can be lifted out of the solution when sufficiently advanced in development to be examined; it will then be found to be stained a deep ruby colour, which will all wash out in about an hour after fixing. I only advise the negative to be slightly washed before fixing and a subdued light used during the operation. I claim it is more convenient when travelling, and you can have more photographic friends in your dark room, and without torturing them with the semi-darkness.

Some discussion followed, after which Mr. ARTHUR HEYWOOD, JUN., read a paper on *The Development of Gelatino-bromide Lantern Plates* [see page 70].

At the conclusion of the paper a number of transparencies were shown on the screen developed by ferrous oxalate and the various developers described in the paper, and some of them intensified or reduced. These were contrasted with one another, and also in several cases with collodion transparencies by professional photographers, but from the same negatives. The latter were by no means always the best.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE usual fortnightly meeting of the above was held in the Technical Schools, Bridge-street, on Thursday, the 24th instant,—Mr. R. Karlewe, Vice-President, in the chair. There was a very large attendance of members.

The minutes of the last meeting (which was special for raising the subscription for the purpose of obtaining larger rooms and accommodation required for the increasing number of members in the Society) were read and confirmed.

Letters were read from the Camera Club, asking for a representative for the Conference, and from Mr. A. Tate, Belfast, conveying the thanks of the Ulster Society for the loan of lantern slides.

Messrs. Thomas Cook, H. A. Dugan, R. Folland, Herbert Miller, A. W. Willis, J.P., and W. L. Willis, were elected members; and Messrs. T. H. Kendrick, W. F. May, and G. E. Wilson, nominated for election.

The CHAIRMAN requested members to volunteer for leaders for excursions during the summer months and to hand in to the Secretaries suggestions as to routes, &c.

Mr. E. C. Middleton exhibited a negative, 12 x 15, of a newspaper taken with a cheap 10 x 5 lens, which showed sharp definition to extreme edges.

Mr. W. R. Osborn presented to the Society, for library, *Photography*, by R. Hunt; and the *Photographic Journal of London*, 1857.

The CHAIRMAN announced that four of the prizes at the late competition not having been won the donors had kindly consented to continue the prizes for the next competition.

The thanks of the meeting were unanimously voted to Mr. Osborn for the present of books, and to Messrs. J. Collier, E. H. Jacques, W. S. Harding, J.P., and W. Tylar, the donors of the prizes held over for competition.

The remainder of the evening was devoted to the exhibition of members' slides, under the superintendence of Messrs. Bonehill and Fowler, of the Lantern Committee. Upwards of two hundred and fifty slides were thrown upon the screen, including many interesting views of Switzerland and the Alps, Holland, &c., and other holiday trips of last year; and some splendid specimens of hoar frost, by Messrs. Archer, Harrows, Harold Baker, Barnett, Hutton, Bonehill, Fowler, Greening, Gollrey, Harrison, Jacques, Marley, Miller, Osborn, Pumphrey, Pickard, Southall, Tittley, Thomason, and Wakelield, the whole showing marked improvement on former exhibitions of members' slides.

Messrs. Harold Baker, E. H. Jacques, and Charles Pumphrey presented the slides they exhibited to the Lantern Committee, and the thanks of the meeting were voted to these gentlemen.

The Council have decided on taking a suite of rooms at the Grand Hotel, Colmore-row, for the new rooms of the Society.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES' PHOTOGRAPHIC ASSOCIATION.

A LECTURE was delivered by Mr. J. R. Payne on *Photography, Past and Present*, in the Lecture Hall of the Literary and Philosophical Society, Newcastle, on Thursday, January 24. There was a large audience.

The lecturer at the outset referred to the fascination of the art of photography, its spread amongst amateurs, and the rapid progress it had made in public departments. Amongst the numerous photographic associations their

own Association took a prominent position. During the last three or four years there had not been an exhibition of photography held in any part of the United Kingdom of any importance where that Association had not been well represented, and on each occasion they had carried away awards. The lecturer then described in a local manner the chemical action of light, and urged upon amateurs generally the great importance of their devoting attention to the character and quality of light. He traced the history of photography during the past century and detailed the different processes, papers, and experiments that had been adopted by various workers, commencing with Scheele, and proceeding on step by step to the Daguerreotype, waxed paper, and albumen processes. The important labours of Moser, Niepce, Crookes, Hardwich, Archer's collodion process, the various dry collodion processes, and the collodionisable process of Sayce and Bolton, were all of them explained. The introduction of the gelatino-bromide process was next explained in detail. Lantern slides made by the various processes referred to by Ferrier, York, Bolton, Traill Taylor, Payne, Green, Lee, Wilson, and others, were shown on the screen by Mr. Ridgway, of Sunderland. The various printing processes—albumen, gelatino-chloride, collodio-chloride, gelatino-bromide, platinumotype, cyanotype—were severally dealt with and examples shown. Commencing with Niepce's bitumen process, and instancing Daguerre's method, the many photo-mechanical processes were each explained, including those of Fizeau, Mouton, Lechevalier, Lecomte, Fox Talbot, Swan's carbon process, the Woodburytype, collotype, photo-lithographic, and other methods. Examples of these were shown, as well as specimens contributed by Green, Bacon, Parry, Wilson, Laws, Eastman, and others. The lecturer read a letter which he had received from the Rev. F. Hardwich, M.A., who said: "At the date of publication of the first edition of my photographic book it is not too much to say that almost nothing was known of the chemistry of photography. The best operators worked by rule of thumb. The late Prince Consort got up a committee to examine the cause of fading of silver prints when he found that those taken by himself and others were not permanent. He gave 50*l.* towards the experiments, and I made them in the laboratory of King's College; you will find a report in one of the old journals of that time. I worked harder, however, at the chemistry of collodion than at anything else, and found it a hard nut to crack. These two points, however, proved to be the crucial ones:—The fibre of the cotton must be parcellised by using excess of oil of vitriol; this gives toughness to the film and intensity to the negative; secondly, the pyroxyline must be the lowest, and not the higher and explosive variety; this produces a smooth flowing collodion which sticks well to the glass. With reference to dry processes, in my opinion Major Russell's tannin process was the best of the old methods. Your lecture will, I am sure, be a very interesting one." As proof of the rapid progress which photography had made and the important position it now held in scientific, artistic, and industrial pursuits, the lecturer explained how the manufacture of photographic apparatus and its appliances had resulted in the formation of a great industry. The publication of photographs in various forms, the illustration of magazines, and the reproduction of pictures, showed in an unmistakable manner the position the art of photography held with the public.

The lecture throughout was of an interesting character, and the practical hints upon the art were warmly appreciated, especially by amateurs, who formed a large portion of the audience.

DEVON AND CORNWALL CAMERA CLUB.

AT the last meeting of the above Club, Mr. W. Gage Twedy in the chair, Mr. R. MURRAY read a paper entitled *A Retrospect by an Old Photographer, with a Few Hints to the New Generation*.

The lecturer began by saying that some forty years ago, when he first commenced the art, photography was very different to what it now was. It was then surrounded by a mysterious halo of wonder; its study was confined to a very few patient and simple-minded people, and processes were all slow in every sense of the word. Apparatus was then solid, made for all time, and the cameras then in use would not now be called portable, being huge brass-bound chests made of wood specially selected for its strength and weight. There were no lenses with wonderful, unpronounceable names, no conflicting developers, no squabbles of rival inventors, and no photographic journals. The calotype process was his favourite one, as, being on paper, it was light and easily carried about; the equipment for the 10×8 photographs taken by him in Egypt would have been a very heavy load for a camel if glass had been used instead of paper. It was quite enough as it was. In his opinion the brilliancy and transparency of collodion plates had not since been equalled. Collodion, of course, had its disadvantages, which had led to its abandonment. One required to carry about a dark tent, chemicals, and water, &c., whereas now nothing was taken but the camera complete and a few ready-prepared plates. As a sample of the amount to be carried in the olden time, he instanced Mr. Wilson, of Aberdeen, driving up to the Blair Athol Hotel in a four-horse coach laden with the necessary apparatus for taking his photographs. The lecturer then stated that nowadays any one could take a photograph; to secure an artistic one was, however, quite a different affair. A really good photographer was to the manner born, with special aptitudes. He should be clever with his fingers, neat and orderly in his habits, patient and hopeful, and, above all things, should possess a fair allowance of brains, having also a keen appreciation of the beauties of nature. He recommended that a beginner should commence with a quarter-plate camera, and stick to one make of plates and one developer until he had mastered the subject. Then a larger size might with advantage be attempted; he thought 10×8 the smallest "picture," but he preferred 12×10. He thought "ordinary" plates more useful than "extra rapid," which latter were difficult to manage and were seldom required except for instantaneous pictures. He asked them always to carefully consider the subject before exposing a plate, remarking that one really good artistic picture was worth a dozen bad ones. As regarded plates *versus* films, he thought the former better for portraiture, but the latter for views, principally on account of their lightness, freedom from breakage, and the absence of halation. He devoted a few remarks to composition, avoidance of straight lines, proper proportion of foreground, middle distance, and sky. He advised every one to do his own printing, many a fair negative being labelled by careless printing. Beginners should not be unduly puffed up by the praise of their friends, but should always be ready to take hints from their more experienced associates. In conclusion, he recommended the art to all, as giving

plenty of exercise both to body and mind, occupation, and enjoyment, and, in his opinion, every photographer should be a happy individual.

Major BARRINGTON BAKER, while cordially agreeing with most of the lecture, took objection to the statement that 10×8 was the smallest camera that should be used. He pointed out that complete with, say, three lenses, &c., its weight would be some thirty pounds, and that this was more than most amateurs would care to carry any great distance. In his opinion, half-plate was the most suitable for ladies and whole-plate for gentlemen; few cared to go much larger on account of the weight.

Several specimens of collodio-albumen, coffee, calotype, and Eastman paper negatives were handed round for inspection.

The next meeting will be on February 6, when Mr. A. A. Carnell will give a demonstration—*Contact Printing on Bromide Paper*.

YORKSHIRE COLLEGE PHOTOGRAPHIC CLUB.

THE annual exhibition of lantern slides was held on Friday, January 25, in the Chemical Lecture Theatre at the College. There was a very large attendance of members and their friends.

One hundred and thirty-eight slides were contributed by Messrs. C. H. Rothamley (President), T. B. Davies, H. B. Hall (Secretary), and Herbert Ingle, Professor E. H. Jacob, and Messrs. A. E. Nichols and H. Pocklington. All the slides had been produced during the past twelve months, and were entirely the work of the exhibitors. The subjects were chiefly landscapes and architecture from the counties of York, Lincoln, Leicester, Warwick, Oxford, Merioneth, and Somerset, and Scotland and the Isle of Man; but a few sea-pieces of figure studies were also shown.

At the next meeting, on February 28, there will be a discussion on *Fine Art in Photography*.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

THE fortnightly meeting of the above Society was held at their studio on Wednesday evening,—Mr. S. W. Allen in the chair.

The Hon. Secretary of the Cardiff Naturalists' Society attended and explained the views of his Committee *re* photographing places of historical interest in the neighbourhood for permanent record.

An arrangement was made by which the Society undertake to act upon any suggestion that may be thrown out by the Naturalist Society with this object in view.

Mr. George Davidson, Secretary of the Camera Club, was duly elected an honorary member, and was requested to represent the Society at the Club Conference held in March next in London.

The lecturer for the evening, Mr. C. MURRELL, gave a lecture on *Hydroquinone as a Developer*. From the specimens passed round for inspection, the lecturer has evidently been very successful in his researches in this new phase of photography.

Mr. Annibal Pinheiro will give a lantern exhibition on Wednesday next; subject—*Brazilian Scenery*, from photographs taken personally. All photographic friends are invited.

PAISLEY PHOTOGRAPHIC SOCIETY.

THE Lantern Section of this Society held a lantern meeting in the Free Library and Museum on Thursday night last, which was a great success.

Mr. R. HARRIS, the Vice-Chairman of the Society, briefly stated that this was the first of a series of exhibitions they intend holding during the next few months.

Mr. RASTALL (the Secretary) stated that they were trying to inaugurate a system of exchange of slides with other societies, with the view of adding variety to the exhibition.

Mr. Mure then exhibited by the lantern with the limelight two hundred and twelve slides. A box containing seventy-eight was sent from Dundee, and they were all exceedingly pleasing. Mr. Fleming, of the Glasgow Amateur Association, showed a number of good slides, and the Society was represented by Messrs. Mure, Rastall, and Thomson.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

THE annual meeting of the Society was held on January 2,—The President, Mr. Frederic Graff, in the chair.

The annual reports of the Treasurer and Executive Committee were presented and ordered to be filed.

The average attendance for the ten stated meetings during the year was forty-six.

The active and life membership, December 31, was reported as one hundred and eighty-two. During the year thirty-six new members had been elected. There had been five resignations and one death, making a net increase of thirty members.

The election for officers and Committee for 1889 resulted as follows:—*President*: Mr. Frederic Graff.—*Vice-Presidents*: Messrs. John G. Bullock and Joseph H. Burroughs.—*Executive Committee*: Dr. Herbert M. Howe, Dr. Ellerslie Wallace, and Mr. William A. Dripps.—*Treasurer*: Mr. Samuel M. Fox.—*Secretary*: Mr. Robert S. Redfield.

The *PRESIDENT* congratulated them upon the prosperity of the Society, which so ably maintained its reputation and influence in advancing the interest now so general in the useful, instructive, and pleasurable pursuit they were all engaged in. They had reason to feel proud of the papers read and of the work of the members from time to time exhibited. They had every reason to look forward to a year even more full of improvement than the past, which, while it has not been remarkable, perhaps, for any very startling new methods, has most certainly brought forth many valuable improvements on old ones. The introduction of new supports for the sensitive medium as substitutes for glass, increased sensitiveness of films, and more portable apparatus, have added to the

facility of working and given renewed inducement for amateurs to indulge in photography as a study and amusement.

Mr. Bartlett exhibited several photographs which were interesting from a historical point of view, the property of Mr. Julius F. Sachse, of Philadelphia. They were the work of Mr. Langenheim, one of the pioneers in American photography, and antedated the days of collodion. The impressions, which date about 1850, were made from silver albumen glass negatives upon plain paper without toning, and represented a portrait of Mr. Langenheim, one of President Fillmore, a view of the Treasury building at Washington, and what seemed to be an instantaneous view of Niagara Falls with natural clouds. The first attempts at negative retouching were apparent, and the importance of the process indicated by the signature of the retoucher appearing on the prints.

Correspondence.

Our Correspondents should never write on both sides of the paper.

CAMERA CLUB CONFERENCE.

To the Editor.

SIR,—Will you kindly permit attention to be drawn in THE BRITISH JOURNAL OF PHOTOGRAPHY to the forthcoming Camera Club Conference which will take place at the Society of Arts on Tuesday and Wednesday, March 26th and 27th.

The Conference will be presided over by Captain W. de W. Abney, C.B., B.S., F.R.S., who will open the proceedings at 2 p.m. each day.

At the same time an exhibition of apparatus will be held in the Library of the Society of Arts, and there will be a collection of member's photographs at the Club rooms.

An international exhibition of lantern slides is being arranged for the evening of the 26th, and at the conclusion of the Conference, on the 27th, the annual Club dinner will be held.

On the Monday previous to the Conference, a smoking concert will be given at the Club.

Full particulars and programme of papers to be read, and other arrangements, will be announced later.—We are, yours, &c.,

G. DAVISON, } Hon Secs.
E. G. SHERRA, }

Camera Club, 21, Bedford-street, W.C., January 29, 1889.

DALLMEYER'S PATENT DIAPHRAGM SHUTTER.

To the Editor.

SIR,—I am surprised that Mr. Dallmeyer should have taken the trouble to notice seriously the ridiculous pretensions of Mr. C. Purcell Taylor. As one of the persons to whom the shutter was confidentially shown in its various stages, I have much pleasure in corroborating the statements of Mr. Dallmeyer, and I need not advert to the matter further than to inform you that I saw the instrument in its present form at Mr. Dallmeyer's establishment in January, 1888—a period at which Mr. C. Purcell Taylor was totally ignorant of the optical requirements of a photographic shutter, probably even of its functions!—I am, yours, &c.,

A. E. HAYMAN.

5, Chandos-street, Charing-cross, W.C., January 28, 1889.

[Mr. C. Purcell Taylor has sent a further short communication, intimating that he has only read the first paragraph of Mr. Dallmeyer's letter in our last issue of the JOURNAL, and that the "matter will be decided in due course by the proper authorities," whatever this may mean. Would not Mr. Taylor have acted more wisely had he read the whole of Mr. Dallmeyer's letter, and also that of Mr. Beauchamp, and then treated the subject on its merits? The dicta of those gentlemen are also endorsed by the letter of Mr. Hayman. The evidence being thus against Mr. Purcell Taylor's allegations, the matter here terminates.—Ed.]

CARBUTT'S FILMS.

To the Editor.

SIR,—When writing a few weeks ago about the price of these newly advertised films, I promised that when I had tried them I would give your readers the benefit of my experience. Through the courtesy of Mr. J. Carbutt, I received, with very little delay and carefully packed, a dozen 3½ x 6½ of these films, some of which I have duly tried, notwithstanding the very unfavourable weather we have lately been having. The films appear slightly thicker than the Frodman film, and a good deal stiffer; they are as polished as glass at the back, and very flat; no signs of peaking at the edges, which is so often the case when gelatine forms the support. They preserve this stiffness in the developer, as water does not seem to affect them in any way, and they can be lifted out and examined as easily as glass. When fixed, they were absolutely transparent and clear. To dry, they are hung up by one corner in a warm place, and the drying takes place quite as quickly as with a glass plate; the film curls inward, but remains perfectly plane and free from cockling,

and if, when dry, it is placed between the leaves of a book or under press for a few hours it becomes quite flat. In fact, I cannot imagine a more perfect substitute for glass, of which they possess all the good qualities without any of the drawbacks. The emulsion with which the films I tried were coated was the most rapid made, and I consider they are fully equal in rapidity to the best English plates I have used; they give, even with short exposure, a vigorous and brilliant image. The coating is very even, and free from defects. I should say, from the colour of the emulsion and its slowness in fixing, that it contains a good deal of iodide of silver.

Though my experience has been short with these new films, I can safely congratulate Mr. Carbutt on having put on the market a perfect film. Its only drawback is the price, and I do not despair seeing this come down with increased demand and improved methods of manufacture of the support, which is at present much higher than glass.—I am, yours, &c.,

GEORGE MANSFIELD.

A PHOTOGRAPHIC SOCIETY FOR BRIGHTON.

To the Editor.

SIR,—Will you allow me to state that a Photographic Society has been started for Brighton and the neighbourhood? The following resolutions passed at the preliminary meeting will make the terms of membership clear:—"1. Ladies and gentlemen, amateur or professional, shall be eligible for election. 2. That the annual subscription shall be five shillings, with an entrance fee of two shillings and sixpence, which fee, however, will be remitted in the case of the first forty members, or those submitting their names to the Society before February 7th." Any further information may be obtained from—Yours, &c., W. H. REAN, Hon. Sec. (pro tem).

36, Vernon-terrace, Brighton, January 28, 1889.

GUTTENBERG'S MAGNESIUM LAMP.

To the Editor.

SIR,—I notice in last week's JOURNAL a criticism of my magnesium lamp by "Junius," and will feel much obliged if you will kindly publish this in answer to the same. In the first place let me state that you published the provisional specification only, and in the complete specifications I have made several essential modifications.

I now proceed to take up "Junius's" criticisms point by point. He displays his ignorance in saying that the burning of a magnesium train would be a new method of dividing glass. The only effect of burning a thin train of magnesium powder mixed with a combustible compound on the smooth side of a stout piece of ground glass is, that after the first ignition the glass becomes indelibly marked along the course of the combustion, and after that no change occurs, as a sediment is deposited which is not affected by further ignitions. I may here mention that I have discarded the use of gunpowder for chlorate of potash and kaolin used as a mechanical separator, because the gunpowder robbed the magnesium of much of its actinic light; and a train of the mixture I now use will, on a given length, give an exposure of a certain duration within an inappreciable fraction of a second as any number of trains of the same length and quantity of mixture. The intensity of the illumination will vary according to the amount of magnesium powder used.

I have just dealt with the question of the desirability of using gunpowder, and need not say any more on the subject. The lamp, after an exposure, can be cleaned with a dry duster and need not be very carefully done, and as for the light being obstructed that is all moonshine, as the powder is burned directly on the glass, and the light comes through on to the sitter without passing through a thick cloud as one would assume from what "Junius" says. As regards the direction and area of the light, the former may be nicely adjusted, and the latter is not confined to the small space of glass, because of the diffusion which naturally takes place, and which is increased by the intervention of a tissue-paper screen between the sifter and lamp.

Lastly, the "fearful and wonderful" part of the apparatus exists only in "Junius's" imagination, which would be wholly dissipated by a personal inspection of the same.—I am, yours, &c.,

W. GUTTENBERG.

29, Triangle, Queen's-road, Bristol, January 28, 1889.

To the Editor.

SIR,—"Junius" having formed so wrong a conception of Mr. Gutenberg's lamp, I think it only fair to the inventor to say that he invited me to see it experimented with. The results obtained were far ahead of many that I have seen produced by some flash lamps, and my conclusion was that it is a most practical apparatus.—I am, yours, &c.,

16, Royal Promenade, Clifton, Bristol,

GODFREY ALLEN.

January 29, 1889.

IVES' SATURATOR.

To the Editor.

SIR,—In reply to Mr. Ives' letter in last week's JOURNAL, I write to say that I have not had the pleasure of seeing or trying the American-made saturator, and so my remarks applied to the English one. No doubt, as Mr. Ives has shown so much ingenuity in designing the saturator, he, or the English maker, will presently find a way of making the joints sound

without the application of soap, either before or after screwing on the cap. I find the screw-valve for the filling opening, as fitted in the modified Broughton-Hardwich oblong saturator, some three or four years since, is quite sound now, so probably a slight modification in this direction, or by using an indiarubber cork (or a specially prepared ordinary cork), the little difficulty can be got over.

In case I did not make myself quite clear in the short article in the *ALMANAC* (and there are one or two typographical slips I see), I now say that I found the U form saturator, with flannel roll inside, give a steady and satisfactory light.—I am, yours, &c.,

G. R. BAKER.

London, January 29, 1889.

COPYING OIL PAINTINGS.

To the Editor.

Sir,—I am afraid "Pictor," in his last voluminous communication, has somewhat lost sight of that element of common sense he so emphatically refers to. He says that when "Glycerine, &c.," was suggested, he and others concluded it was to be applied *per se*. For instance, it is a very usual mode of expression to say such-and-such a negative is developed with pyro or ferrous oxalate—now here common sense comes in and suggests that the pyro or ferrous oxalate should be used with water, and not rubbed on to the film *per se*. In the absence of common sense such might be the case; so with the application of glycerine or many other things which will, in all probability, suggest themselves to "Pictor" now his attention is called to it. May I ask "Pictor" if he has ever himself seen an oil painting damaged or destroyed by the application of glycerine either *per se* or diluted? and, if he has, *when* and *how* did it occur? No one is too old to learn, but from my own experience I never saw or heard of any harm accruing to oil paintings treated in the manner under discussion, or knew of anybody else who did, but as positive is better than negative evidence, it will be interesting, not only to the writer, but to others, to hear particulars of such a case, and all the detail therewith connected.—I am, yours, &c.,

EDWARD DUNMORE.

SHAKESPEARE AND PHOTOGRAPHY.

To the Editor.

Sir,—Mr. Lyonel Clark will find in *King John*, act iii., scene 1:—

"To solemnise this day, the glorious sun
Stays in his course, and plays the alchemist;
Turning with splendour of his precious eye,
The meagre cloddy earth to glittering gold."

I am, yours, &c., EDWARD HEALEY.

10, Endymion-terrace, Finsbury Park, N.

[Replies have also been received from Mr. J. Tilfor; Rev. F. Brown; Mr. A. E. Smith; G. B.; Messrs. H. Whitfield, William Lang, jun., and others.—Ed.]

Exchange Column.

*. No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

An old Chippendale mirror, perfect order, very handsome, in exchange for a 12x10 or 10x8 tourist camera with back.—Address, Ash, 143, Barking-road, Essex.

Wanted, 12x10 long extension field camera with lens and three backs, or roll holder; exchange, light roadster safety (Baylis & Thomas).—Address, A. F. THORPSON, 114, Acree-lane, Briston, S.W.

A modern bellows camera complete, not less than 12x10, also a nine-inch condenser for enlarging lantern, also a Kodak, wanted in exchange for full value in drawings by members of the Royal Society of Painters in Water-colour.—Address, A. I. Church-street, Leamington.

Answers to Correspondents.

PHOTOGRAPHS REGISTERED:—

R. W. Sharp, Hamilton, N.B.—Two photographs of James Alston Dykes, Procurator-General for Lanarkshire.

V. R.—Your letter is libellous and cannot be published.

A FRIEND.—The weekly *Journal of Patents* sells at sixpence.

ALPHA.—Grained plates can be obtained at Hughes & Kimber's.

PUZZLED AMATEUR.—See reply to "J. Hoddington" in last issue.

GARRE.—One gramme is equal (approximately) to fifteen and a half grains.

FAIRPLAY.—Certify your statements by supplying names and other particulars.

THE FAIRLEY PHOTOGRAPHIC SOCIETY are desirous of exchanging lantern slides with other societies.

AMATEUR (Nottingham).—Do not carry the glazing of side and roof close to the end, but leave about three feet opaque.

P. Q.—1. Chloride of sodium is nearly as soluble in cold as in hot water.—2. The person named is a charlatan.—3. Thanks.

HYDRA HYDRATE.—Sodium hydrate is also known as caustic soda. Washing soda is the carbonate, but baking soda is the bicarbonate.

D. S. L.—It is certainly in bad taste to have a tree or other straight vertical line right behind the sitter's head and growing, as it were, out of it.

SILVER IODIDE.—We do not think that the spots arise from metallic particles in the paper, but rather from the subsequent treatment to which the paper is subjected in course of printing.

G. A. GROVE asks: "1. Is the School of Photography in Vienna open to ladies?—2. Will it be open in March and April?—3. Can one join in the middle of a term?—4. What are the terms?"—Can any reader answer?

GEORGE STRAHAN.—No patent can be taken for a moveable or revolving platform on which to pose a sitter, this having been in use for many years; but you may obtain protection for new or improved means for effecting such movement.

DAVID MALCOLM.—It is impossible to give directions in the shape of a formula; but the general principle governing rapidity is long cooking of the emulsion coupled with the employment of ammonia nitrate of silver. It is a matter of experimenting.

JAMES DAVIDSON.—1. The articles for beginners were reprinted in our *ALMANAC* for 1888.—2. The fumes of ether, in moderation, have no ill effect upon persons working with collodion.—3. Jabez Hughes's *Manual* of from ten to fifteen years ago will give the required instruction.

THE PHOTOGRAPHIC DEPARTMENT (Leven Ship-yard, Dumbarton) inquires: "What is the best method for preserving home-made sensitised paper from becoming yellow, either by putting the preserver into the silver bath or otherwise?"—In reply: Float the paper upon a weak solution of tartaric or citric acid.

SULPHITE.—Either of the plans will be suitable if the front portion be made of glass. If any buildings obstruct the light it may be diffused by glazing with ground glass or covering the present glass with tissue or waxed paper. By putting the glass much light is stopped. It might pay you to have an expert examine your studio.

A. J. R.—By placing your lenses in a shorter tube, so as to bring them closer together, a larger angle of view will be included, but not on the same size plate. In order to obtain this it will be necessary to insert lenses of shorter focus. Our advice is not to attempt to make any alteration yourself, but send it to a competent optician to be done.

J. G.—It is quite within the bounds of literary propriety to make extracts from the columns of *Punch* confining yourself to the typographic matter and properly acknowledging the same, but the case is different in regard to the illustrations. In this case you must apply to the publisher for permission, which, considering the object in view, would, we think, be most readily accorded.

F. EVELYN THORNHILL.—On dissecting the transparency we found that the stain was not a chemical one, but arose from a physical cause, the gelatine being disintegrated at each spot. We washed it with a solution of cyanide, in case of imperfect fixation, and while wet the opacity had quite disappeared, only to reappear again when dry. We then gave it a coat of varnish, by which the transparency was permanently restored.

C. T. FRANKLAND.—We have no knowledge of the plates named. With regard to the quality of plates now placed in the market, while it is quite possible that there are some that are not all that can be desired, yet it is very certain that at no previous period have those of such excellence been produced. This applies also to apparatus. If any photographer will have the "cheap and nasty," instead of better and more reliable productions, it is their own fault, and they do not deserve to succeed. If we judge of the state of the art in some parts of London by specimens which we have seen at some doorways, we should say that your strictures are well deserved, but you know there are photographers and photographers. Take a more cheerful view of things.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, February 6, 1889, will be on *Photographic Lenses and the Work for which they are best suited*.

HUDDERSFIELD PHOTOGRAPHIC SOCIETY.—February 6, 1889, Lantern exhibition by Mr. T. K. Mellor. Lady friends of the members are invited. February 20, A discussion on *Developers and Developing* will be opened by a short paper by the Hon. Secretary. Members whose subscriptions are unpaid should communicate immediately with the Treasurer.

THE GRIMSTONE SHUTTER.—A further improvement of a revolutionary nature has been effected in this well-known shutter, which is now constructed to give both instantaneous and time exposures. There are two index fingers, both emanating from the same centre: by one of these the tension of the actuating spring is increased or diminished, by which a considerable range of rapidity is imparted to the "instantaneous" movement. The other index point places the action entirely at the command of the operator, so that he can either have the quicker movement or one which can be protracted indefinitely. The mechanical action is pretty and of a nature not likely to get out of order, and, what is of great importance, it effects its various movements without a jar when operated, as it is, by a pneumatic ball. Provision is made to keep it open while focussing, and it will prove a valuable addition to the numerous shutters now in the market. Messrs. Wratten & Wainwright are agents for this improved Grimstone.

No. 1501. Vol. XXXVI.—FEBRUARY 8, 1889.

ASTIGMATION—ITS NATURE AND EFFECTS.

THERE is no one who has at any time undertaken the task of delivering a lecture on photographic lenses but is invariably forced to the conclusion that not one hour, but many hours, would be necessary in which to get the subject treated in anything like a reasonably comprehensive manner.

One of the branches of photographic optics upon which, for the reason hinted above, Mr. Beek did not treat in course of his lecture at the Society of Arts last week, but which slightly obtruded itself during the brief discussion which ensued, was that of Astigmatism. Time precluded the possibility of this topic being entered upon during the discussion, but we now make the attempt to explain, in language so simple as to be understood by the tyro in the art, the meaning of the term, and the nature of the distortion or defect to which it refers.

Astigmatism, or astigmatism, is a defect in a lens or combination of lenses in virtue of which a difficulty is experienced in obtaining the same degree of sharpness at the sides or margin of a photograph as at the centre. This property is scarcely treated of in any standard works on Optics, because of there being little necessity, except in the case of photographic objectives, to recognise the transmission of rays obliquely through lenses.

To discover astigmatism, the easiest way for the photographer to proceed is to make a circular hole, the size of a sixpence, in an opaque sheet of paper or card, and close alongside of it cut out a cross of this form +, that is, one in which the lines stand in a direct vertical and horizontal direction. The arms of this need not exceed one inch in length. It will suffice if a disc and a cross be cut out of white paper and pasted upon a black ground.

To the object thus prepared the camera is now directed, and all the stops having previously been removed from the lens, the disc and cross are focussed as sharply as possible on the centre of the ground glass. Now rotate the camera so as to bring these images to the margin, when, if the screen be moderately large, the following phenomena will be observed if the image is examined with a magnifier:—A general falling off of sharpness in any case, and, on an attempt to obtain better definition by refocussing, the little disc loses its circular shape and becomes elliptical.

By racking the lens in or out, it will be observed that when it is turned in the oval image stands up and down, while if it be racked out to the point of greatest sharpness, the elongation of the oval is in the horizontal direction. The image of the cross, too, behaves in a strange manner, for when the lens

is racked in so as to secure the greatest sharpness of the image of the now oval disc, the horizontal lines of the cross become so indistinct as to be sometimes barely discernible, the vertical lines remaining sharp and distinct; while upon racking out the lens until the oval stands in a horizontal direction the vertical lines of the cross, formerly so sharp, are now indistinct, the horizontal ones alone being defined.

It will thus be seen that the rays which are transmitted obliquely through a lens come to a focus at two distinct places, one of these foci being nearer to the lens than the other, and this constitutes astigmatism. The skill of the optician is taxed to have both these foci brought as close together as possible, while preserving flatness of field in the greatest possible degree. It is possible to reduce astigmatism to a minimum, but this is effected at the expense of rounding the field, the flattening of which introduces as a concomitant the evil referred to.

Hitherto we have been assuming the employment of a lens with full opening; but by the insertion of a stop the astigmatism is reduced, at least as regards its photographic effect, and in this is found a convenient remedy for the defect and one open to every photographer to utilise.

In this brief article we have dwelt only on the perception and effects of astigmatism. Its cause optically must remain to be treated on a future occasion.

CHOOSING A CAMERA.

OUR present object is not to write a treatise on the myriad forms this piece of apparatus assumes in the workshops of modern makers, but rather to draw attention to those points which are more frequently ignored in selecting an instrument for future real service. A little common sense brought to bear on a question which is too frequently decided by caprice, or an inclination to sink all other considerations provided a particular one is carried out, will be very useful.

Rigidity, portability, and lightness, combined with facility of erection, should be prime considerations in the construction of almost every camera; but there are many on the market at this present time ingeniously designed and beautifully made, but which, in actual service, could only be characterised as "rickety." Yet, because they possess some particular quality to perfection, those purchasers who consider this quality the one main essential of camera construction are too apt to look lightly for other qualities that are really equally needful. One

man must have the lightest camera capable of being constructed, while another takes his stand on the rapidity with which it can be erected. A third will not work at any which will not extend to about a yard long, while a fourth thinks that one with every possible motion to the front is the *summum bonum* of camera design. A fifth looks upon one that has an infinity of ingenious and complicated motions as the acme of perfection, which yet another finds in the shape of the bellows, whether conical or square. And so on, we could describe individual requirements in number sufficient almost to fill a JOURNAL.

In purchasing a camera, therefore, the first point for consideration should be the class of picture it is to be used for, and the lens or lenses to be used with it. Many amateurs nowadays spare no money over lenses, and they possess batteries of them enough to make their less fortunate brethren's mouths water; yet they do not always choose wisely. For example, there are many useful working forms of camera that do well with lenses of light weight, but which would be both shaky and apt to get "out of square" when weighted with a heavy optical combination in front, so much so as to be useless. Again, great length in a camera may at times be a vast gain, and enable subjects to be secured which would be quite unphotographable with those of ordinary length; but such an instrument is useless in this direction unless the user possesses a lens to correspond. Take, for example, a half-plate camera extending to twenty inches, what use is the extra ten inches to a photographer who possesses only a six-inch focus lens, or, mayhap, a five and an eight, the latter by no means usual? The extra cost entailed by such an instrument would be far better spent otherwise. Length in a camera is very like wide-angle power in a lens; it can only be utilised when certain conditions are present: an eight-inch wide-angle lens would belie its name when used on a half-plate, and a twenty-inch extension to a camera a useless encumbrance unless with a fourteen or fifteen-inch focus lens.

We have lately seen several cameras purchased within the last three months, at a high price, with swing backs, of a most inefficient character. In the first place the swing was far too limited, and, secondly, there was no side swing. Now, when a photographer is educated enough to know that a swing is good for other purposes than that of restoring the parallelism of lines made to converge through tilting the camera, he ought to be able to see that the side swing is really more useful than the vertical for ordinary work, and, seeing how much quick work—snap exposures, &c., with full aperture—is attempted, the use of a side swing, as well as the vertical, is of great importance for foreground objects.

Turn we now to another aspect of the subject. Many cameras are made for which it is specially claimed that they can be used with short-focus lenses, yet which are useless for the purpose in many instances. They may answer quite satisfactorily when the plates are used "landscape" fashion, that is, with the longest side parallel to the ground, but the moment the plate is used vertically, and particularly if the lens has been lowered, which has to be done for interior work at times, they are useless, as the lower part of the plate presents a picture of the base of the camera extension. There are patterns of repute, and many of them now made, which will not permit any lens of shorter focus than an eight or nine inch on a 12 × 10 plate. The majority of subjects would be embraced, it is true, by such a lens, but when interiors, for example, are likely to be required, every camera should be

rejected which will not, without showing the structure of the camera on the negative, allow a negative to be produced with a lens with maximum focus of half the length of the largest plate the dark slide will carry. If this point be looked to it will be found that a large number of popular cameras will not stand the test.

We will conclude our remarks with a reference to another very important requirement ignored in, perhaps, more than half the cameras brought out within the last ten years. It is seen more especially by those possessing a good range of lens power for use with varieties of subjects. We allude to the inconvenience of a projecting tailboard when short-focus lenses are used. Taking again, for a type, a well-made 12 × 10 camera of an old and favourite construction, hinged tailboard, with screw focussing arrangement and moveable front, we find that if a seven-inch focus lens be used for, say, the interior of a church, the board is so much in the way that focussing becomes a practical impossibility for those objects thrown upon the lower part of the plate. The full force of this drawback is only seen when short-focus lenses are used; it is only a slight inconvenience at other times, hence many photographers have no practical acquaintance with the defect, for grave defect it is. Some makers of modern cameras have a knowledge of this, and have devised ingenious modes of shifting either the body part of the camera or the front, so as to bring the ground glass immediately at the back, with no intervening obstacle between it and the observer. This, we say, is done in some cameras, but our final advice in this regard is, let the operator beware that when the ground glass is so placed, and the moveable front also withdrawn from its more usual position at the front to allow for the use of short-focus lenses, the former error we described does not show itself, we mean the inclusion of the camera base within the field of view. In all these latter points we can only now say—*caveat emptor*.

WITH a view to bringing about uniformity in the sorting of slides for photographic exhibitions, Mr. F. York in another column makes a suggestion which is both practical and valuable. It consists in affixing numbers to each in a manner which he fully explains.

AMATEURS will soon be considering their work for next season, and the apparatus they will adopt. Lantern slides are now very popular, and stereoscopic ones will probably be equally so during the coming season; therefore we advise every one to provide himself with the means of taking them. Most of the modern cameras for outdoor work of the half-plate size and upwards are usually constructed for taking binocular pictures, and those which are not can be easily adapted for the purpose. The most awkward cameras to apply are those with a conical bellows, in which the front is narrower than the distance necessary between the two lenses. But the difficulty is not insurmountable. Two lenses, though desirable, are not really necessary, as the stereoscopic effect may be obtained with one. But in this case the lens must be fixed to a sliding front, capable of being moved horizontally the same distance that twin lenses would be mounted apart.

ANY quarter-plate camera, or one capable of taking lantern-size negatives, can also be utilised for stereoscopic work. All that is necessary is to have the means of moving the camera, laterally, about three inches between making the two exposures. This is easily managed by having a small board to screw on to the stand in the same manner as the camera, with guide pieces in which the latter can slide. Although a repeating back—to take the two pictures on one glass—is a great convenience, it can be dispensed with, and the ordinary dark slides used. Two lantern-slide negatives, taken, say,

three inches apart, are all that is required to make a stereoscopic picture. Of course, when only one lens is used, care must be taken that the two exposures are identical. If they be made on two separate glasses, they should be developed simultaneously in the same dish, in order to secure equal density in each. Amateurs who have only small apparatus need not be discouraged from using it for stereoscopic photography, for, as a matter of fact, all the earliest stereoscopic pictures were taken with monocular cameras.

MUCH of the fugitiveness in silver prints may, no doubt, as stated in our American notes last week, often be traced to over washing. By this we do not wish it to be inferred that the picture can be too perfectly freed from the hyposulphites; but that any soaking in water after this is accomplished serves no purpose whatever, and is injurious to the permanence of the picture. Long contact with water, particularly in warm weather, is liable to set up a decomposition in the albumen, as well as the fixing material of the paper, and this cannot fail to act deleteriously on the image. There are some photographers who think the "hypo" is removed from their prints after four or five hours' washing; but with the view, as they say, of "making assurance doubly sure," leave them in running water all night, so that they receive in the end from twelve to fifteen hours' soaking. This is a mistake. There is no question that the quicker the hyposulphites can be removed from the paper and the print dried, the better it is for the stability of the picture. By careful treatment, and continuously changing the water, a couple of hundred or more prints can be effectually washed in from two to three hours, and a smaller number in still less time. Experience has demonstrated that prints from which the hypo has been eliminated in about the time mentioned are more permanent than those made under similar conditions which have been washed for twelve or eighteen hours.

It does seem a pity, as soon as a thing becomes popular, that its popularity should be arrested by its being made too commonplace. Manifestly is this the case with pictures on opal glass. The quality of the pictures may now be said to have degenerated into the "cheap and nasty," for some, now to be seen in the shop windows, are anything but a credit to the process by which they are made, or to photography itself. Some little time back we mentioned that the *favor* for this class of picture was on the wane amongst the *élite*, and now we learn that some of the better class of fancy stationers have discontinued keeping them. Inquiry is often made as to the process employed for these cheap productions. The majority of them are made by the ordinary carbon process, but some are by the Woodbury process. In the latter case the prints are first made on paper, and afterwards transferred to the glass.

As we predicted it would when these cheap carbon opal pictures were put into the market, their introduction has had a material influence on the business in highly finished "porcelains," both as regards price and demand. Expensive portraits on opal glass are not so highly esteemed now as they were a few years back. This is to be regretted.

WHAT facilities photographers possess nowadays for accomplishing what a few years back would be impossibilities! yet how frequently do they neglect to avail themselves of them! Here is a case in point. The week before last several photographic copies of three letters were required, on the following day, to be produced in one of the Law Courts. Somewhat late in the afternoon one of the solicitor's clerks was sent with the letters to several different photographers to try and get them copied, but none would undertake the work in the time. Later on another clerk took the matter in hand, and tried other photographers, giving them to understand that expense was no object provided the copies were delivered in time. Finally, with this understanding, one photographer undertook the order, and, as daylight had departed, this is how the work was executed:—The letters, in turn, were fixed on the copying board, the focusing being previously done by measurement—the exact equivalent focus of the lens being known. Then some magnesium ribbon was burnt just above, and a little behind, the camera. One or two trials determined the exposure

necessary, and thus the three negatives were secured. They were then washed, as well as time would permit, and dried by alcohol. The prints were made by gaslight, on bromide paper, and were ready for delivery in the morning. The work proved satisfactory to the customer, and the cheque for it equally so to the photographer, for the charges, though necessarily high, were not questioned.

THE possibility of obtaining views of buildings at night by the agency of the magnesium flash light is now fully established. At the meeting of the North London Society on Tuesday evening a 15 x 12 print of a building was shown. It had been obtained by the light from a Hart's patent lamp, situated at a distance of sixty feet from the building. The charge of magnesium was only sixty grains, and the lens—a rapid rectilinear—was worked with a stop of $\frac{1}{2}$. There are numerous architectural subjects of which, owing to crowded thoroughfares or like causes, it is difficult to obtain a photograph during the day. But when night has set in, and the traffic has become quiescent, then is the chance for the photographer, who, with a magnesium light, is enabled to capture shops, warehouses, and other scenes, otherwise unattainable.

It is not such a great number of years since the natives of the Hawaiian Islands in the Pacific were not quite so far advanced in social, commercial, or any other kind of culture as we know them to be at present. For at least a decade the inhabitants of Honolulu have rejoiced in the possession of a daily newspaper, and evolution has been carried a stage further by the formation of a camera club there. We learn from official sources that there are about fifty amateurs in these islands, which ought to be enough material to make the organization prosperous and useful. The public has an interest in it, as one function to be assumed by the camera club is the holding of exhibitions. The photographers of Honolulu have our best wishes for their success in their incorporated capacity.

At the club room of the Photographic Society of India (Calcutta) a daylight enlarging camera has recently been fitted up, together with all the necessary apparatus for manipulating large sheets of sensitive paper. India has recently increased in its number of photographic societies, the most recent being those at Madras, Bombay, and Allahabad. At the latter, an A B C photographic class is held after the ordinary business is transacted.

A FOREIGN chemical journal is responsible for the statement that in hot weather ready-mixed hydroquinone developers spoil in less than a week, while in cold weather they last two or three weeks, and also that all gelatine films developed with alkaline developers strip off in warm weather. It suggests as a prevention to the latter that the negative be soaked in a strong solution of salt after development.

THE employment of alcohol methylated, so as to render it unfit for use as a beverage, free of tax in the arts and manufactures, has lately been receiving attention from the Congress of the United States of America. The Bill before Congress contemplates the use of bonded warehouses for storing spirits of not less than 80 per cent. proof; the removal of such spirits free of tax from such warehouses to bonded store rooms to be used in certain manufacturing establishments. The proprietor of any bonded alcohol may, according to regulations, methylate the spirit so as to render it unfit for use as a beverage, and remove it free from taxation. As in Great Britain and in Germany, such methylated spirits cannot legally be purified, heavy penalties being prescribed for such purification.

ON THINGS IN GENERAL.

It must have been a rare treat for those members of the Camera Club, who were present on the occasion, to listen to Mr. Common's most interesting discourse on *Photographing the Nebulae*. To hear a "past master" of the science discourse so instructively, and withal so genially, upon one of the most important branches of our

science would be well worth travelling far. If every beginner in photography (I am afraid I may give the same advice to many an old hand) would cut out of the JOURNAL where it appears, and paste in the most prominent position in his dark room the last reported of Mr. Common's remarks in the discussion, and would attend to them, we should have a deal more good work and a deal less futile talk than we now get. I will repeat them here: "Everybody has found what I have found myself, that it is of infinitely greater importance to get a middling developer and know its practice than to be butterflyling about from one formula to another." Here is the very essence of common sense and the very best advice. Moreover, Mr. Common has added a new word to the photographic vocabulary—"butterflyling." It is so expressive that I do hope it will stick, and be of frequent use as long as the state of things it describes continues. More, it will help to kill by ridicule the formulæ-mongering of the plate makers and the preposterous system they recommend for compounding the developer.

I admire, too, the lecturer's ready way of admitting that he could not explain the cause of the variation in the size of the photographic star discs, which vary as the magnitude of the stars themselves—it was a "special dispensation of Providence," and he looked to photographers to explain it.

The discussion or conversation bearing on this point was by no means satisfactory: more pertinent remarks might have been made on this still little understood subject. It was surprising to learn that Mr. Common did not back his plates, though certainly the brand he mentions needs it as little as any.

I was interested in the discussion at the London and Provincial Photographic Association meeting, in *re* magnesium powder. Little seems now to be said of the mixture of magnesium powdered and chlorate of potash, yet it will give a splendid light with less trouble than any, and I do not think it at all likely to be dangerous if stored.

At the same meeting, one of the speakers alluded to a useful pigment made from the bitumen found in old mummies. The first oil colour-box I ever had contained a tube of "mummy brown;" but I quickly learnt its treacherous nature. It ought never to be used, as it cannot "dry"—a painful fact well instanced in the works of some of the older English painters. It is stated that in the cellars of the National Gallery there lies an oil painting, placed upside down in the hope of the eye gradually coming back to its proper place from the middle of the cheek to where, owing to the use of bitumen, it had slowly descended after being correctly painted. I have never seen the picture, but the story is old.

Those who wish to try "Junius's" plan of exploding magnesium with explosive sawdust may save themselves the trouble, danger, and mess of making it by buying Schultz powder, which is the same thing specially prepared for firing in gems. I should think the plan would be very good, and far superior to gunpowder, with its unpleasant fumes. By-the-by, the inquiry is made as to where to purchase the absorptive cotton wool spoken of. Any chemist would obtain it; some dealers send it out unspecified when best cotton wool is asked for. On one occasion I got in a two-pound parcel of wool, and at once detected it by its curious and unpleasant feel. It has a peculiar dry touch, that causes a sensitive cuticle to experience the same unpleasant sensation that is felt upon handling objects after a long immersion of the fingers in hot water. It is splendid for making into pyroxyline; it goes down like a damp sponge instead of an air-bell-imprisoning piece of ordinary wool.

I am very much surprised that no one has accepted Mr. Haddon's challenge as to the impossibility of producing an image on any but a portion of the plate when a small piece of the lens only is used. I respect Mr. Haddon's practical and theoretical skill, so much that I think he must really have been attempting to hoax his audience. Taking the report in this JOURNAL (p. 20), he describes how a portion of this picture was absent when a small segment only of the lens was exposed to the object. This is, no doubt, a perfectly correct account of an experiment, and if left there would be rather a puzzle to many; but when he next says, "I again say, and I say most emphatically, that unless a considerable portion of the lens is uncovered, the light which passes through is confined to a portion of the plate only." If, now, he had omitted the phrase "passes through," his assertion would be correct. It is the very fact that a portion of the light received does

not pass through, that explains the matter. The lens he treated in the manner described would be not a pin the worse in use, either as regards duration of exposure or otherwise, if he permanently painted a narrow black ring round the margin of its anterior surface. The explanation is that rays received at a certain angle near the margin of the lens pass through the front surface and then are lost, owing to their being received upon the blackened edge of the glass before they have a chance of reaching its posterior surface. If the lens were a single positive, with sharp edges, this would not occur.

"Pictor's" last literary production presents no new argument, consisting, as it does in the main, of excited reasseverations of his previous errors, and accusations of dishonourable practices on my part, which will only raise a smile wherever my letters have been read, so uncouthly false the accusations are. The courtesy with which I have treated him seems lost upon him; I therefore have no resource but to cite authorities which show that this writer, who makes such professions of knowledge, is, as regards these particular subjects, quite ignorant. On his first appearance he writes, "There are many colours—such as the lakes, Vandyke brown, ivory black, &c.—which would scarcely dry in twelve months, unless specially ground in drying oil, or mixed with varnish or some other siccativ." The sentence is meaningless; the colours are dry to start with, and no one in the possession of his faculties would purposely mix artists' colours with non-drying oil. "Pictor" writes, "The objection to them (nut and poppy oils) is that when they are not boiled they will scarcely dry in less than twelve months, as a rule." This is what Watts says of nut oil in his *Dictionary of Chemistry*, vol. iv., p. 145, "It dries more quickly than linseed oil;" and Cameron, in his work on oils and varnishes, says (p. 44), "Poppy oil dries and keeps well." I have before pointed out that "Pictor's" knowledge of the subject of oils appears to be derived from some particular little bottle or two he possesses. "Pictor" writes, "I have a bottle of refined linseed oil and a bottle of nut oil in use at present, both purchased from the same artists' colourman; the linseed is nearly colourless, the nut has rather more colour than common linseed oil." I quote Watts again (same page): "Walnut oil . . . commonly called *nut oil*, is greenish when newly prepared, but becomes pale yellow by keeping;" (vol. iii., p. 702) "the cold pressed oil of fresh linseed is pale yellow."

All this from one who "more than a quarter of a century ago commenced an extensive range of experiments, conducted under counsel from the highest living authorities on the manufacture of artists' colours, varnishes, oils," and "Pictor" has utterly and needlessly dragged in a question of my personality. With regard to his personality I will not hazard a guess, but I will say that his remarks, involving as they do a display of complete ignorance of the subject he gave such earnest study to, rather negatives the idea that he is a house painter, for the latter would know more of the subject. I conjecture that the varnish he is most familiar with is negative varnish. If he be an operator who has picked up a little knowledge of painting, it is very creditable to him, but does not make him an authority. As for myself, I have received medals and certificates of competency from the South Kensington authorities which for years have qualified me to act as a teacher, under South Kensington rules, in various branches of drawing and painting.

FREE LANCE.

PHOTO-MECHANICAL JOTTINGS.—III.

PHOTO-LITHO in half tone differs totally from line work from beginning to end. In line work the photographer does merely a mechanical transfer of a subject previously drawn by an artist. In half tone work the photographer works from an ordinary half tone negative, breaking up the half tints by reticulating the gelatinous coating upon the paper or glass used to produce the required transfers upon.

Half tone transfers for stone are made direct upon paper from an ordinary negative, or upon collotype plates specially prepared and dried at a very high temperature. For the direct transfers Husband's process is the best published, and with certain precautions yields perfect results. The paper used must be extra stout to carry the thick film of gelatine necessary to produce the requisite reticulation or grain. The best way of getting a good even coating of gelatine upon the paper is to coat it twice, suspending the sheet to dry the second time by the opposite edge it was suspended from the first time. The

coated paper must be thoroughly dried, then rolled up and kept in an air-tight case, as it is very hygroscopic, and unless so stored gets sticky and spoils.

The drying after sensitising should be done in a box heated to 90° or 100° Fahr. The box to be ventilated top and bottom, so as to get a gentle current of warm air constantly circulating, then the film of gelatine will dry evenly and quickly. If the box be a closed one the gelatine will melt at much less than the proper temperature. During the exposure under the negative the whole of margin of print must be protected from the light by means of an opaque mask, else the print will be unmanageable when on the board for inking up on account of the strong curl. Do not stint the size of paper used. A negative 10x8 should have a piece of paper at least 14x10, with at least a tail piece of three inches at one end, so as to give a good hold at the joint of inking up board.

Do not allow the print to soak too long before inking up, else the half tones will not hold the ink, in this case a sponge charged with methylated spirits rubbed over the print will save it. Winstone's photo-litho transfer ink may be used for inking up these prints, and save the trouble of mixing it at home, which is not an agreeable operation. Don't get too much ink upon these transfers, else they are sure to squash in transferring, and do not omit the final bath of tannic acid and bichromate, nor the exposure to light when dry. This final exposure to light of the whole transfer renders the whites incapable of absorbing too much moisture when in the damping-book, so lessening the chance of a squash in transferring.

For transfers from collotype plates the Petch process yields good results, as does the process of Swan, in which a trace of calcium chloride is added to the gelatine. The following formula, now first published, has given, in my hands, and in those of several pupils, excellent results, and with absolute certainty.

The requirements are:—A collotype oven fitted with levelling screws, and capable of being heated to a temperature of 150° Fahr., and plates a quarter of an inch thick coated with a substratum of silicate of soda and beer. These plates are placed in the oven, and, after being accurately levelled, are warmed to 130° Fahr., then coated with the following mixture in the proportion of 200 c.c. to a plate 15x12:—

Nelson's amber gelatine	200 grammes.
Glycerine	2 c.c.
Water	500 "

Soak the gelatine till quite soft, then melt at a temperature of 140° Fahr., heating the water up gently from cold. When dissolved, add the following, dissolved, and heated to 140° Fahr.—

Bichromate of potash	30 grammes.
Ferricyanide of potassium—the red prussiate ..	10 "
Nitrate of potash	5 "
Water	500 "

If the salts are powdered, solution will be more rapid.

Strain through muslin, then coat the warm plates, returning them to the oven to dry, the temperature being maintained at 150° Fahr., which will dry the films in from three to four hours. When dry, expose under a reversed negative rather flat but well exposed. The printing being continued until the image can be seen with all details at the back of plate.

When sufficiently exposed to light, soak in an upright vessel—changing the water at frequent intervals—until the whole of the yellow bichromate is removed, then stand the plate away to dry. The plate outside the picture must be protected from the light, or the ink margin will render the task of pulling a clean transfer very difficult, besides dirtying the blanket and backing sheets. The operation of pulling transfers from these plates is the same as printing from collotype plates, and will be treated under that head, merely remarking here that they are, after damping, rolled up with a leather roller charged with transfer ink, and the print made upon scotch transfer paper.

The operation of transferring these pictures to stone must be entrusted to a skilful lithographer, it being quite beyond the skill of a photographer quite unused to the transferring even of an ordinary line job.

W. T. WILKINSON.

WHICH IS THE BEST POSITION FOR A SHUTTER—BEHIND THE LENS, OR IN FRONT OF THE PLATE?

[A Communication to the London and Provincial Photographic Association.]

THIS question, which has been submitted to us for solution, and elicited some difference of opinion, has induced me to jot down the following remarks as a small contribution to the debate. I do not claim any originality, for most of the ideas have been frequently

expressed before. My aim is to bring the question clearly before you, to draw attention to some points which have been overlooked, and, if possible, to reply to the inquiry.

It is, I think, understood that the class of shutter is of the curtain pattern. I believe it will be conceded on all sides that such a shutter, if placed in front of the plate, will allow the full power of the lens to work on each portion of the plate as it is being exposed. It will also be conceded that such a shutter placed behind the lens will cut off a portion of the light during the opening and closing of the lens. These two facts seem to have disposed of the question in some minds, and the conclusion has been arrived at, that a shutter placed in front of the plate must be the better. Such an opinion I do not share, although I am willing to admit that in the case of very brief exposures, under special conditions, a shutter placed in front of the plate would give the best result.

In the manufacture and use of a shutter there are other circumstances to be considered besides the one of illumination, and were we to disregard them we might, perhaps, find after all that the shutter did not give us the results we expected of it, and that our choice had fallen on the wrong kind. The motor, the material of which the curtain is made, the size of lens, and the size of plate, are all of them important factors, and besides these there are the questions of distortion and blur which are deserving of consideration.

We will assume, for argument sake, that we have a shutter in front of the plate, that the opening in the curtain is four inches, and that the length of the plate to be traversed is four inches also. You will require four inches of curtain to protect the plate before exposure, and four inches to cover it after. The minimum length of curtain must therefore be twelve inches, and the length to be unwound to effect exposure at least eight inches. If the shutter is worked at the speed of $\frac{1}{15}$ second per inch, the plate will receive an exposure of $\frac{1}{5}$ second. We will suppose the lens used is a six-inch rapid symmetrical. This has a diameter of one inch. If we placed the shutter behind the lens, and fixed the length of curtain to be unwound at eight inches, the same as in the former case, we can use an aperture of seven inches in the curtain. The speed being fixed at $\frac{1}{15}$ second, as before, the exposure would last $\frac{1}{15}$ second. But in this case the illumination is not equal throughout, consequent upon the opening and closing of the lens. For this we must deduct one diameter of the lens, which leaves us with six units of exposure as against four units in front of the plate, or an increase of fifty per cent. But the exposure lasted $\frac{1}{15}$ second, as against $\frac{1}{5}$ second, which is an increase of seventy-five per cent. in time. If we reduce the exposure to four units in both cases, we can do so by shortening the aperture in the curtain behind the lens by two inches. The result then will be, that we obtain the same effect of light upon the plate by an exposure of $\frac{1}{5}$ second with a shutter in front of the plate, as against $\frac{1}{5}$ second if the shutter is used behind the lens.

Again our opponents will say, this being the case, why do you not admit the former position is the better? We have assumed equal conditions throughout, but, I ask, can they be maintained? Suppose the spring we use is worked at its highest tension, and the curtain will bear no more strain, we shall then have attained our highest speed with the shutter in front of the plate. But with the shutter placed behind the lens we have less curtain to unwind, and we can increase its breadth considerably. In other words, we have less to move, consequently more speed; and greater strength of curtain, owing to more breadth, therefore more latitude for increase of tension.

In respect of length of curtain we have room for a gain of more than thirty per cent.; and in respect of strength, measured by the breadth of curtain at the weakest part, probably room for gain of 400 per cent. at least. I arrive at these figures by assuming the curtains are eight inches and six inches long for what is unwound, and three and a half inches and one and a half inches for breadth respectively.

I shall probably be met by the answer that we can reduce the slit in the curtain before the plate to very narrow limits. This brings us to the question of distortion as against blur. If we have a curtain passing across the plate and the slit is narrow, objects will be shortened or lengthened, curved or partially shut out, according to rate of movement in object or shutter in the same or opposite directions. On the other hand, if we place the shutter behind the lens, the exposure, assuming it to be longer, will produce a small amount of blur. I say small amount because we are enabled to strengthen our springs so considerably, if my assumptions are correct, that the fractional difference in time must be very small, comparing the two positions of shutter. Now of these two drawbacks I certainly prefer a slight blur to distortion. Some would say, pictorially, it is an advantage, as imparting an idea of motion, and I do not think they are wrong. I am not certain as to the speed that can be obtained with shutters of the curtain pattern affixed to the lens, but I believe I shall be within the

mark if I state that exposures of $\frac{1}{10}$ second can be given with a lens one inch in diameter. This would meet almost any requirements.

Thus far I have taken the ordinary conditions of a detective camera; and, assuming the conditions correctly stated, I should reply to the question asked, that a shutter placed behind the lens would be preferable. The diameter of lens as compared with length of plate being determining conditions in the problem, were a portrait lens used the result would be different. I have not had time to work out the question, but I think the shutter in front of the plate would then be best. If, however, we go to larger sizes of plates and lenses of the rapid symmetrical type, there will be an increase of advantage in using the shutter behind the lens, for I find lenses are smaller in diameter in proportion to the plates for which they are used, as we ascend in the scale of size. We must also bear in mind the factors of weight and bulk. A camera would have to be made larger if the shutter were placed in front of the plate, and cameras increase in weight according to the square and not the length of the plate. Thus I am again brought back to the answer I have already given, which is, that the back of the lens affords the better position for a shutter as compared with the front of the plate.

T. EVERETT.

PHOTOGRAPHIC OBJECTIVES.*

FACTS AND FALLACIES REGARDING THEM.

THE next step is cementing. This is a delicate process, for although in each part of the work heat has been used, a much higher degree is required, and the danger of cracking the lenses is increased. It is no ordinary occurrence to lose lenses in this work, or, for that matter, at any point of the process. Great care must here be observed to prevent the cement from turning yellow, and thus disturb the transparency of the lens and thereby cause loss of light. The lenses are next temporarily fixed in the mounting and are ready to be examined in the camera. Now comes the moment of suspense. Focussing on an object—and for this purpose I consider a large flat screen covered with printed matter containing various sizes of letters, or a large map hung against a perpendicular wall, the best—the first thing which comes to our notice is the focal length of the objective. It may be one-half of that which was figured upon, or twice as long. However, if not correct, we make note of how much it varies and proceed to examine the image. This may be sharp and brilliant in the centre and gradually become more indistinct as it nears the edge, and may remain indistinct near the edges under any amount of focussing; or it may have the same fading out of the image toward the edge when the central portion is sharp, but this may be brought out clear by change of focus; or the image may be such that it cannot be sharply focussed at any point. There is yet one possibility, but a strong improbability, that the image may be quite sharply defined over the entire screen; this of course is the most favourable condition. After making note of whatever the appearance may be, we proceed to determine the coincidence of visual and chemical foci. As is well known, there are, photographically speaking, two sets of light rays emitted by every object. Those that form the image on the screen, and which are most perceptible, or the visual ones, are made up by the red, yellow, and orange colours of the spectrum; whereas those which make the photographed image, or the chemical rays, are formed by blue, green, and indigo, which are the least discernible, and it is a problem of some difficulty to bring both sets to form an image in one plane. To determine this, we proceed to make an exposure on a plate. Before doing this, however, we must be assured of three things: First, that the ground glass is flat; second, that the plate which we intend to use is flat; third, that the plate when exposed will be in exactly the same plane as the ground glass. I lay great stress upon these points because on them depends a reliable result, and then because with many plates and cameras these conditions are not fulfilled. If you will go through a package of plates you will find some almost perfectly flat, others that are convex, and others concave, the deviation being fully as much as one-sixteenth of an inch, and in larger plates even more.

I do not mention this in the way of finding fault with the plate manufacturers, because ordinarily, and particularly when stops are used, it is of little moment, and because it would be almost impossible to furnish selected flat plates at the present prices. The Eastman roll holders I have found well adapted, because the film passes over a fixed and flat back which remains constant in its relation to the ground glass. If the ground glass is flat, then flat plates should be selected, and if the ground glass be concave, then plates corresponding to it should be used. I believe that, as a rule, where care is observed,

* Continued from page 72.

slightly concave ground glass in plates are used, because they come in this way and this form favours the lenses. The one thing, however, which should be insisted upon, and which I am sorry to say is not always the case, is that the film side of the plate should be exactly in the plane of the ground glass when it replaces it. To determine this, the following plan, which I think is used by manufacturers of cameras, is effective.

Take a straightedge and allow it to rest upon the face of the frame of the ground glass which rests against the back of the camera. Cut a small wedge of wood and insert this between the straightedge and ground glass as far as it will go, and mark the edge in line with the straightedge when it fills up the space. Now take a plate which is suited to the plate holder and which is known to be flat, and place it in this, and by the use of the straightedge and wedge proceed as above with the ground glass. It is unnecessary to say that the marks should agree exactly, and if not should be made to do so.

These precautions are alike necessary for the optician and photographer, whether for the purpose of determining the quality of the lens or for making comparisons between several lenses, and it is a test which every camera ought to undergo. After the plate has been exposed and developed, we may find that although we have a sharply defined image on the ground glass, the one on the plate is very indistinct, which shows that the chemical foci may be shorter or longer than the visual. To determine the extent of variation a number of exposures must be made, placing the ground glass within or beyond the visual focus until as sharp an image is obtained in the negative as on the ground glass. We now have all the principal data to enable us to proceed with the correction of the lens. First is the focal length, next the spherical aberration, then the amount of distortion, and last, but for the present most important, the difference between visual and the chemical focus.

To attempt to correct any one of these qualities will disturb the others, and not only that, they are often to such an extent antagonistic that to improve one will considerably augment another fault. It is not within the province of this paper to show what the likely changes would be which should be followed to improve the objective, but I can indicate what some of the results would be which would arise. For instance, if the visual and chemical foci do not coincide, it is evident that the objective is chromatically over or under corrected, and if the objective would otherwise give a good image, the inner or cemented surface would probably be changed; this might very naturally affect the focal length, which in a telescope objective would hardly be noticed. The focus of the lens might easily be doubled before the proper correction would be reached, and then changes would again be necessary to bring the focus to the proper distance, which would again disturb the chromatic correction as well as, perhaps, the spherical, which latter designates the amount of curvature of the image. Thus, a change of one-sixteenth of an inch in the radius of one of the inner surfaces, which would hardly be noticed in an ordinary lens, might lengthen or shorten the focus of the photographic objective several inches. The changes which sometimes occur are often surprising and inexplicable, even to one who is accustomed to them. It may be found that the amount of spherical aberration is so great that no amount of changing will bring it to the proper standard. One means of partially overcoming it would be the decrease in the size of the lenses, which would mean that they will admit less light, and consequently be slower.

The thickness of the lens which causes the distortion must be accurately determined. However, we will assume that the various corrections are finally combined as far as is possible, and the skill of the optician must determine to what extent they will be. It may be possible to combine the spherical and chromatic aberrations sufficiently to make the former acceptable, and a new series of experiments will have to be undertaken, based on a combination of new glass.

After a lens which meets the ideal of the optician is completed it may be said, "We can understand that the first lens has involved a great amount of work, but after the completion of the sample none of these difficulties will arise." To a certain extent this is true, but it must be remembered that the optician's work is almost entirely empirical. Each lens is an experiment; there is an individuality in each which cannot be overlooked. A lens is rarely, if ever, perfect when completed, and each one is a special study. There are certain features which rarely, if ever, change when working under the same formulae and using the same glass, such as coincidence of visual and chemical foci, centring, and size; but others, such as homogeneity and refrangibility of glass, sphericity of surfaces, length of focus, are variable, and often can only be reached after repeated trials, and in many instances cannot be obtained at all.

EDWARD BAUSCH.

(To be concluded.)

INTENSIFICATION BY MERCURY.

There is no doubt but that up to the present time mercury, in some form or other, is the favourite means employed to confer density on gelatine negatives, as it was in the wet collodion days, if black-and-white images were required. Gelatine does not lend itself so kindly to intensifying processes as collodion did, being much more liable to stains and markings, even if considerable care is exercised, than did the process it has superseded. A solution of bichloride of mercury will alone change the colour of the image by converting portions of it into chloride, if the solution is used weak and its application not long continued; and this method is adopted by at least one experienced and well-known photographer. The image so altered will naturally change on exposure to light, the chloride of silver darkening, and it entirely depends on the evenness of the chloride formation if the negative becomes irregular in density or not; the chances are that in time such intensified negatives will become defective and patchy.

The doubtful permanency of negatives that have received only treatment with bichloride of mercury has induced the generality of photographers to follow it up by some oxidising or sulphurising solution, in order to add permanency in addition to strength. The most favourite solutions are of cyanide of silver, ammonia, or sodium sulphite. The greatest difficulty is to regulate the intensity with any of them. It seems that to ensure a thoroughly even film the bichloride must be allowed to act until the image is whitened through equally, as may be seen by examining the back of the plate. When this is effected after treatment by bichloride of mercury, the image will consist of chloride of silver and subchloride of mercury, and to make it available as a negative these chlorides must be decomposed into either sulphurets or oxides.

The sulphur compounds have a somewhat more non-actinic colour, and when much increase in density is required are preferably used, much depending, however, on the strength of the solutions; but if only a little extra strength of negative is required, a more slowly acting solution is advisable. Amongst the sulphurising compounds, sodium sulphite of about ten grains to the ounce of water is very good, and not liable to stain, even if the bichloride of mercury is not carefully removed by previous washing.

Another good plan, simple and inexpensive (although under any circumstances the expense is scarcely worth considering, it never being great), and one which I think is not generally known, is, after the usual whitening by bichloride of mercury and well washing, to put the negative in a bath of lime water until it is darkened evenly throughout. This gives a very even and good colour, and is permanent as any other method of mercury intensification, the metal being reduced to a state of oxide. Lime water, for the information of those who have not made it, is easily prepared by taking, say, half a pound—the quantity is immaterial—of freshly-burnt lime, not slaty, place it in an earthen pan or jug, and just cover it with cold water. The violent action which takes place in a few minutes being allowed to subside, half a gallon of cold water added, the whole stirred together and poured into a bottle and allowed to settle, the supernatant solution of hydrate of lime being poured off as required, and filtered, if necessary, for use. The only precautions necessary are to keep the bottle filled up with water, giving it a good shake after each addition, and well corked, only pouring off as much as is required for immediate use, as on exposure to the air insoluble carbonate of lime is formed at the expense of the hydrate, and the solution gradually becomes inert. This will be found to give an exceedingly even and pleasant coloured negative, and will not cause brilling. If the intensity is judged to be not right, a bath of hyposulphite of soda, a good wash and treatment with dilute hydrochloric acid, will fit the negative for any other kind of intensification that may be thought better.

E. DUNMORE.

THE CONSTRUCTION OF PHOTOGRAPHIC LENSES.

[A Communication to the Society of Arts, by Conrad Beck.]

THE paper you have done me the honour to ask me to read to-night will, owing to the extent of the subject, be very incomplete. It is of course, in a single evening, impossible to do more than indicate a few of the main principles that are involved in the construction of photographic lenses; and if in some of my preliminary remarks I weary you by the repetition of matter that "every schoolboy knows," I must ask you to excuse me, as I feel that the only safe way to approach a subject of this kind is entirely *ab initio*.

The theory which has explained the majority of the phenomena of light is that it is produced by vibration in a medium we call ether, which is assumed to permeate everything. Although this theory may be superseded—or, more correctly, developed—it is quite sufficiently certain for us to accept its results for the purposes of this paper. The vibration is held

to be a wave motion which takes place at right angles to the direction in which the light is moving. The distance between two consecutive crests or hollows of the wave is termed a wave length. This wave length does not depend on the intensity of the light, and for the same coloured ray it is always the same when travelling through the same medium. But should this ray pass into another substance of greater density—as, for instance, from air into water—its wave length will be shortened, and will give rise to the phenomena called refraction. Without, however, entering fully into the causes, let us merely examine this fact we call refraction. We can at once see, by the very simplest experiments (as, for instance, placing a stick in water), that the light which comes from an object in a denser medium is bent on its journey, and as rays of light in one medium alone are experimentally proved to move in straight lines, this alteration of direction or refraction must take place at the surface of the two media. Precisely the same result ensues when light passes from a lighter into a denser medium. But it is observed in the two cases that the direction of the refracted ray is different. In Fig. 1, where the ray passes from a

lighter into a denser medium, it will be noticed that the refracted ray turns towards the perpendicular to the surface which divides the media, whilst when it passes from a denser into a lighter medium it turns away from this perpendicular, or the normal as it is called. We find, by experiment, that if we take the ray which cuts the dividing surface at right angles it will pass direct into the second medium without refraction, and that rays which impinge on this surface at different angles are refracted to a different extent. It only remains to discover whether there is any law which these refractions follow which can determine at what angle any ray will emerge in a given medium when entering it for another given medium. It is curious to find that Ptolemy, in the second century, made observations of the angles of incidence at a surface, and their corresponding angles of refraction. Vitello, a Polish mathematician, in the thirteenth century, did the same, but the law of refraction was not discovered until 1621 or so, by Willebrod Snell. This law (which is established by experiment) states that when we are dealing with two media of different density, the sine of the angle of incidence, divided by the sine of the angle of refraction, is equal to a constant quantity, which is called the index of refraction; and it was also observed that the incident and refracted rays lie in one plane. The angles of incidence and refraction are the angles which the incident and refracted rays make with the normal; thus, in Figs. 1 and 2, the angle of incidence is the angle ABX (α), and the angle of refraction is the angle CBX (β).

Let us now consider light coming from a point, O, in one medium (A), Fig. 3, say air, and entering another medium (B), which we will suppose

Fig. 3.

denser, say glass. Light will impinge on the dividing surface, which for the first case (upper portion of Fig. 3) we will consider flat, at all angles. Let us first note, as we said before, that the ray which strikes the surface at right angles goes through it without refraction. All other rays will be more or less bent, and the law of refraction shows us that those in which the angles of incidence is greatest have greater refraction in proportion than rays of smaller angles of incidence, for if we differentiate $\frac{\sin \alpha}{\sin \beta} = \mu$ we shall see that as the angle of incidence is increased the amount of refraction, or the difference between β and α , is increased much more rapidly. In the second case, suppose instead of a flat surface we

take a series of small facets and place them at right angles to each ray, then these rays will all pass through into the glass without refraction; thus, if we have light coming from the centre of a circular surface, it will pass through it without refraction.

Next (Fig. 3, lower portion), let us place our series of facets in such positions that, instead of destroying the refraction of the several rays, we increase it. Let us do this to such an extent that, instead of having a diverging series of rays, we make them converge towards the axis. Now, by properly arranging our plates we can make the three rays, *a*, *b*, *c* (Fig. 3, lower portion), converge to the same spot. But since the number of rays is infinite, we shall need to place a series of plates so small as to be merely points. These points will trace a curve, and the form of this curve will be the necessary shape of the dividing surface of the two media, in order to cause a bundle of rays proceeding from a point, *O*, to converge to some point *O'*, in the denser medium.

Now this is just the proposition we have in photography. It is required to converge the light emerging from one point of the object to a single point on the photographic plate; but as a rule the object is at infinity, and light impinges on the surface in a parallel bundle. The practical photographer must not be misled by this word infinity; it is a relative term, and a distance of twenty feet, for instance, when compared with a distance of two or three inches, is practically at infinity, *i.e.*, we can treat all light which starts from such a distance as travelling in parallel rays. Now the curve which would bring parallel rays to one single point is a conic section, and Descartes showed that if lenses could be made whose sections were ellipses or hyperbolas, they would accurately accomplish this. But, alas! all practical men know that it is impossible to make these surfaces true enough for optical work. One true surface we can make, and that is a spherical one, and this is the one which, for want of a better, we are obliged to adopt. To make it clear why a parabolic or elliptical surface cannot be made, I will merely draw your attention to the fact that, in order to grind or polish a lens surface, a tool must be made of the exact shape of the lens required, the lens must then be ground with emery or some other material until the glass assumes precisely the shape of the tool, and in order to accomplish this it is essential that the glass be moved over the tool in several directions, and that it is at the same time touching the tool over its whole surface during the operation. In practice it is found that the more irregular the motion within certain limits, the more likely the surface of the glass is to be ground equally all over. As an example, let us suppose we wish to make a lens of elliptical shape, the only way in which the glass can be moved in the tool while it remains in contact over its whole surface is by its being revolved on the axis of the ellipse. It is evident that if this be done, as the periphery moves more rapidly than the apex, more will be ground off the edge than the centre, and a true curve cannot be obtained.

What, now, is the effect of using a spherical surface? The rays no longer all meet at one point, and the larger the surface of the sphere we are considering, the more difference is there between the points to which they converge. The error which thus arises—due to the fact that it is necessary for us to use spherical surfaces—is called spherical aberration, and I propose to show what are the devices by which we reduce it to a minimum.

There are only two cases in which it is possible for us to obtain no aberration for light passing through one single surface, and both of these are useless for photographic purposes. The first case we have already mentioned, when the object is placed in the centre of a sphere, but, as we saw, this gave no refraction; the second case is when the distance of the object from the centre of the sphere is equal to a certain quantity, *viz.*, the refractive index multiplied by the radius of the spherical surface. For photographic lenses the radiant point is almost always at a great distance, and its rays being therefore parallel, cannot enter any surface as if they emerged from a point comparatively near to the centre of the spherical surface as this would be.

I shall not weary you by going through the mathematical steps which determine the exact amount of aberration for rays due to refraction through a single surface, but the amount is given by the equation:—

$$\Delta f = \frac{\mu - 1}{\mu^2} (\rho + D)^2 \left\{ \rho + (\mu + 1) D \right\} \times \frac{y^2}{2}$$

Where *f* is the reciprocal of the distance of the point to which the rays converge from the refracting surface, *ρ* is the curvature of the surface, *y* the semi-aperture, *D* the reciprocal of the distance of the radiant point from the surface, and *μ* the index of refraction. In dealing with this equation we must not take the absolute aberration, but take it with reference to the focus, and there is not time to-night to discuss the way in which it varies.

I have previously mentioned that in order to bring a bundle of parallel rays to a point, we require an ellipse or hyperbola; it should be the former when the rays enter a denser from a lighter medium. It is interesting in this connexion to note that the most perfect projection lens in existence, the human eye, has for its first surface (the cornea) a portion of an ellipsoid, whose section would thus be elliptical.

We assume, therefore, that the nearer a surface tends towards the elliptical form, the less aberration it will possess, and it is evident that a convex surface is nearer to an elliptical form than a flat surface, and will therefore give less aberration, whilst, at the same time, it has greater re-

fracting power. And we can further see that the nearer we make this convex surface approach the given ellipse (which is determined by the refractive index) the more we destroy aberration. If, now, we take two refracting surfaces, and form what we call a lens, we at once ask ourselves: "Can we not, by properly combining the two curves, destroy aberration entirely, and yet leave some refraction, for we see that the two do not vary in proportion?" We find that we can make lenses of the same refractive power, but with widely differing aberration; but in spite of this we cannot entirely destroy it with the kinds of glass that we now possess. We should require a material with a refractive index of at least four, the possibility of discovering which is altogether beyond our most sanguine hopes.

It is therefore impossible to entirely correct aberration in one lens. We can, however, largely modify it. I have made a diagram showing the relative amounts of aberration which arise from lenses of various shapes, and you will see that the lens with the greatest amount of aberration possesses four times that of the best form. As a general rule, we can remember that when parallel rays enter from a less refractive medium—say air—into a denser medium—such as glass—the more curved the surface turned towards the parallel rays, the less the aberration; the flatter the curve, or the nearer it approaches a flat surface, the greater the aberration.

I have placed at the top of this diagram a series of convex lenses, all of the same focus, giving their aberrations, and below them a series of concave lenses, also of the same focus (only negative), giving their aberrations. If, now, we take a convex lens and place it next to a concave lens, with just the same relative aberration, we shall neutralise the aberration, but, since the focus is the same, the refracting power will also be destroyed, and the compound lens will have no power to affect light passing through it. But suppose we take a convex lens with the smallest amount of aberration, and combine it with a concave lens of the largest quantity of aberration, although we get the refraction neutralised, we shall get the aberration far more than corrected, and can reduce the focus of the concave lens, and with the focus the aberration, which is dependent on the focus to such an extent that the aberration is corrected and we shall then have left a considerable amount of refracting power, although, of course, not so large an amount as in a single convex lens.

Let us, then, see to what conclusion we have arrived. We have found that light is bent on entering a medium of different density; that we can nearly bring this to a point, but not wholly, by a single spherical surface. That a lens will, to a certain extent, correct the error thus formed, but not altogether, but that a combination of two lenses will completely do so.

We have hitherto treated light as if it were caused by a single vibration of the material we call ether, this vibration having always one wave length which is only altered when the light passes from one medium into another of different density. This, however, is not the actual fact, though in order to explain spherical aberration it was convenient to assume that such was the case.

The effect which gives rise to the sensation of white light in our eyes is supposed to be produced by the combination of a large series of vibrations all acting together on the retina of the eye. If we consider a vibrating ray emerging from the sun or some other powerful light-giving source, we shall find that it consists not of one vibration with a single wave length, but of a great number all travelling together at the same rate, and differing only in their wave length. On more close examination of this ray we shall find that the vibrations consist of some with a long wave length, others with a slightly shorter wave length, others again still shorter, until we have vibrations with exceedingly short waves. In fact, the complete ray consists of an ascending series of vibrations, each having a slightly shorter wave length than the last, and all travelling together.

It is interesting now to see in what ways these various vibrations affect our different senses. If we isolate from a complete ray the waves only that have very long wave lengths we shall find that no effect of light is produced on our eyes; but if we place a thermometer in the path of these rays, we shall observe that these long wave-length vibrations have heating power. Let us now isolate a portion of vibrations with rather shorter wave lengths; we shall find that the effect of heat is still produced, but that our eyes are also affected by these rays, and the result obtained is that we see what we call red light. Isolating again another portion of the vibrations with still shorter wave length, the effect they produce on the eye is again light, but of a different colour—yellow. The next vibrations produce the colours to the eye of orange, green, blue, and violet, in the order of the spectrum, until at last we come to a point where no further effect of light is produced. The vibrations do not, however, cease here. There are vibrations with still shorter wave lengths than those which cause light, and these, together with the green, blue, and violet vibrations are the waves which affect the photographic salts of silver.

One must not suppose that there is any radical difference between these rays beyond the difference in their wave length. They affect our different senses in different ways. The vibrations that are beyond the visible end of the spectrum would give rise to light, except that our eyes are not delicate enough to see them. We have every reason to believe that they are visible to some of the smaller animalcula. The same applies to the heat rays, and if our eyes were but sensitive to them, we can conceive it possible that we should have no need to ask our companions in the room if they found it too warm, we should see if they did so.

(To be continued.)

COLLODIO-BROMIDE EMULSIONS.

Mr. L. C. LAUDY, of the American Museum of Natural History, Central Park, New York, a well-known worker in the collodion processes, has at my request kindly given me a formula which he obtained from Mr. Newton, and which he says at the time it was used they kept secret.

He says they regarded Mr. Newton in those days as the "shining light" in this country on collodion emulsions. The formula is very practical and gave beautiful results, and all looked for a great future in collodion emulsions, until one day gelatine emulsions appeared, and the glory of the beautiful collodion-emulsion departed. The following are the particulars as given by Mr. Laudy (for Newton's emulsions use Ilanec's delicate cream cotton):—

BROMIDE EMULSION.—FORMULA FOR ONE OUNCE.

Silver nitrate eighteen grains to the ounce. First dissolve in ten drops of water; then add five drops nitric acid for each ounce of solution; then add half an ounce of alcohol, in which is dissolved twelve grains bromide cadmium; then add six grains of cotton, shake well and add half an ounce of ether; let it stand twelve hours, then add four grains chloride calcium.

BROMO-IODIDE EMULSION.—FORMULA FOR TWO OUNCES.

Silver nitrate (crystals) thirty grains dissolved in twenty drops of warm water, then add ten drops nitric acid.

Alcohol	1 ounce.
Bromide cadmium	18 grains.
Iodide ammonium	2 "
When these are dissolved add cotton	12 "

Then add the silver solution and shake well; then add one ounce of ether and let it stand twenty-four hours; then add eight grains of chloride cobalt dissolved in a little alcohol. If the iodide is not used let the amount of silver be twenty-eight grains, and add the chloride cobalt after the emulsion has stood for sixteen or eighteen hours. Plates thus made with this emulsion may be at once exposed in the camera after coating and be developed with the following developer:—

Make a saturated solution of neutral oxalate of potash in water, then add to each ounce fifteen grains of pulverised protochlorophosphate of iron, and lastly, just enough citric acid to the solution to turn litmus paper red.

But if the plates are to be preserved in a dry state they should be put in a special solution made as follows, and called:—

JAPAN TEA PRESERVATIVE.

Saturated solution Japan tea in alcohol	1 ounce.
Water	16 ounces.

The tea solution is prepared by soaking one ounce of Japan tea in six ounces of alcohol, let it stand until a strong tincture of tea is made, then add one ounce of the tincture to sixteen ounces of water. Or better, make a saturated tincture of tea in alcohol, and add two or three drops to each ounce of bromide emulsion. After coating, simply wash the plates in one or two changes of water until the oily lines disappear, and rear up to dry.

To make the plate more sensitive, when it is desired to expose it in the camera, while wet flow over the surface the following accelerator:—

Salt soda	150 grains.
Bromide of ammonium	2 "
Water	12 ounces.

* Continued from page 75.

Mr. Laudy has also sent me a copy of Mr. Newton's printed directions concerning the use and manipulations of the plates. His developer, called a stock solution, is prepared as follows:—

Yellow prussiate potash	1 ounce.
Carbonate of soda	100 grains.
Bromide of ammonium	15 "
Water	10 ounces.

After exposure the plate is washed under the tap a few moments to remove the preservative, then the developer, consisting of half an ounce of the above solution, to which four grains of dry pyro has been added, is poured on. The image soon appears, and the development is accelerated by the air by frequently pouring the developer off and on. If more intensity is desired, add to the developer a little more pyro. Fix in hypo solution, one ounce of hypo to four ounces of water; give the plate a good washing and set up to dry. When dry, varnish the plate to protect the film.

Dr. J. J. Higgins tells me the formula he used successfully is that which was employed by Mr. Albert Levy, and known as Levy's emulsion.

(To be continued.)

F. C. BEACH.

THE SOCIETY OF AMATEUR PHOTOGRAPHERS OF NEW YORK.

THE Committee on Papers and Publications send us the following report:—

The work of two successful amateurs was shown on Friday evening, January 18, 1889, at a special exhibition held at the rooms of the Society, 122, West 36th-street. The exhibition opened with Mr. Charles Simpson's illustrations of the "Open Air Statuary of New York," which comprised forty-three views of about forty different statues. In speaking of his work, he remarked that it was the most difficult piece of photography he had ever undertaken. He made all the views with the detective camera and at different times. Of one he made nine separate exposures before he obtained a picture that was at all satisfactory.

The chief trouble was the exceedingly dark colour of the bronze figures (especially when they faced the north), in bringing out the details sufficiently. Again, very undesirable backgrounds would appear when a position was selected which would make the statue show to its best advantage. It was also surprising to note how scant a record was kept by the city of the dates when the statues were put up, the names of their sculptors and designers, and any other interesting information connected with them. He had great difficulty in getting the information. It had taken him about one and a half years to make the collection. There were only two statues of Presidents of the United States in New York City. The pictures were quite interesting as showing the number and variety of statues in New York, and the work reflected considerable credit on Mr. Simpson for the time, perseverance, and energy he had expended.

Following his views were about fifty beautiful slides by Mr. James E. Brush. These included some wonderful pictures of Niagara Falls in "Ice Chains," as the programme stated, and a great many fine landscapes in the White Mountains. One was an enlarged view of the profile on the Profile Mountain, which he had enlarged directly upon the lantern slide plate from the small image on the negative. The result was to bring out the details remarkably clear, making the profile appear much larger, as if one was looking at it with a telescope. It was said that it looked much larger on the screen than one could see it with the naked eye. To enlarge so successfully requires fine lenses and great care in focussing. Another view was of the steamer *Bristol*, of the Fall River Line, recently burned at Fall River. It appeared like a shadow of its former self.

PATENT COMPLETED.

A METHOD FOR PRODUCING PHOTOGRAPHIC EMULSIONS NOT REQUIRING A BASE OR SUPPORT AS PHOTOGRAPHIC FILMS.

No. 4574. EARNEST SIDNEY WILLIAMS, 41, Jones's road, Drumcondra, Dublin, Ireland.—March 31, 1888.

My invention or process consists in a chemical combination, wherein I ensure the presence or contact of a salt of chromium with gelatinous photographic emulsions (known as sensitive emulsions) which are spread on glasses, or other suitable smooth material, and as soon as set or cooled I react on such emulsions with sulphuric acid or any of its compounds, whereby the salts of chromium do not affect in any way injuriously on the compound sensitive silver salts contained in photographic emulsions, provided such emulsions are thoroughly freed from excess of sulphuric acid or its compounds.

Hitherto the attempts to produce photographic emulsions for exposure in the camera, without a base or support to carry the sensitive film, have met with no success to my knowledge. Every endeavour was centred to improve the supports for such emulsions, as paper, collodion, and various other transparent tissues. My attempts were centred to render sensitive emulsions capable of being their own supports.

By my method this can be attained, and consists in the following operations: 1 (make or) prepare a gelatinous photographic emulsion by any of the well-known processes, but containing a rather large quantity of gelatine in its composition, add a certain quantity of a chromium salt, preferably the bichromate of potash or ammonia, while the emulsion is yet warm and in a fluid state, mix thoroughly, spread said emulsion in a dark room upon levelled glass plates, or on any other suitable smooth support such as slate, ebonite, or varnished paper, &c., which have been previously well polished and dusted over with french chalk; leave the emulsion to cool, and when set, I immerse the glasses, or other supports containing the emulsion, into a bath of sulphurous acid or its compounds until the acid has performed its chemical reaction upon the bichromated gelatine emulsion, I then wash it in several changes of water to remove all soluble compounds and the sulphurous acid. Lastly, I dry them in suitable dark chambers, and when quite dry, strip the photographic emulsion from the support.

Thus produced, the emulsions can be made in long strips either to be cut up to the required sizes or suitable for roller slides, without any base or support, neither glass, paper, nor any other transparent, hard, or flexible material, and which can be worked just as well as if such bases or supports were used.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—1. The method or process of chemical combination wherein I ensure the presence or contact of a salt of chromium with gelatinous photographic emulsions (known as sensitive emulsions), and react with sulphurous acid or its compounds, whereby the salts of chromium are rendered injurious on such emulsions by subsequent development of the image after exposure to light. 2. The novelty of such dried emulsions, not having any base or support for the production of photographic negatives or positives, combined with the simplicity and cheapness of its manufacture. 3. That such dried photographic emulsions can be exposed in a camera from either side, and that the resulting picture or image will be contained in the emulsion itself, consequently can be printed from both sides without loss of sharpness of such prints. 4. The perfect insolubility of such dried emulsions, not having any soluble emulsion on its surface. 5. That any photographic emulsion, consisting of compound salts of silver suspended in gelatine, can thus be treated, and be made thick or thin, light and unbreakable, yet pliable and firm.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, last week, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. W. E. Tichenham presided.

Mr. G. W. Atkins was elected a member of the Association.

Mr. EDGAR CLIFTON drew attention to a newspaper report of the accidental death of Mr. Bewley, of Dublin, owing "to the condensed state of hydrogen gas in the bottle" which he was carrying, whatever that might mean. Were iron gas bottles safe?

Mr. J. J. BRIGGS said that Ilin's Oxygen Company, in London, would not fill with oxygen any bottle brought to them for the first time without testing the bottle, for which test they charged a shilling.

The CHAIRMAN remarked that the name of Bewley was well known in connection with mineral water manufacture, in which machinery was used which would give great pressure to gas; perhaps too much pressure had been applied.

Mr. A. HADDON believed that the pressure was eight or ten atmospheres in such machines, and fell to about four atmospheres in the bottles.

The HON. SECRETARY remarked that the meeting had not sufficient informa-

tion as to the circumstances under which the explosion took place to form any opinion on the subject.

Mr. W. COBB exhibited some portraits taken by artificial light by Mr. Barry, of Hull. He thought them to be good, and did not know what light Mr. Barry had used.

The CHAIRMAN thought them to be better than usual. Much depended upon the management of the reflector in such work.

Mr. T. EVERETT then read a paper on *Roller Shutters* [see page 85].

Mr. THOMAS KERR said:—

Since the last meeting I have made a number of experiments that have confirmed me in the opinion I previously expressed, viz., that the best place for the shutter in a camera is as close to the lens as it can be placed. The only exception I can find to this rule would be with a plate of the same width as the diameter of the lens (such as a three-inch plate with a lens of three inches in diameter, a combination we are not likely to have in practical work), in which case there would be shown on an exposed plate a little less movement with the shutter close to the plate than with it close to the lens, but there would be no difference in the exposure (that is, if the shutter with a three-inch opening travelled the whole distance in two seconds each part of the plate would receive one second's exposure in each case). But there will be found a great difference if we go to another extreme, that is, to take a three-inch plate with a three-inch opening in the shutter and a pinhole aperture; now the shutter when close to the plate will have to travel, as in the previous case, six inches to expose and recover the plate in, say, two minutes, so giving one minute's exposure to each part of the plate, and showing on the plate three units of movement on each part of the plate, but as a whole plate (that is, from side to side) showing six units of distortion. With the shutter close to the aperture it will only have to travel three inches, and moving at the same rate as before, six inches in two minutes, it will give a three-inch opening or one minute's exposure, having the full power of the light on the whole plate, and will show three units of movement, but no distortion. Here are a number of plates exposed by means of a curtain shutter in a camera in which I could use the shutter in either of three positions, viz., close to the plate, immediately behind the lens, or in front of the lens, the lens used being a rapid symmetrical of about five-inch focus and one-inch diameter, the shutter with an opening of three inches. To obtain a steadily moving object, I fitted up a bicycle wheel with square tablets of white card, the wheel revolved by means of a clockwork motor, and I so obtained a regular speed. The negatives shown are certainly the best when the shutter was used close to the lens. I next fitted up a pair of stout rollers, seven feet long, in a frame six feet apart, and put on these a band of calico, two yards wide, with black laths sewn across exactly parallel to the rollers; on one roller was fitted a pulley and hand connected to a small motor giving regular speed, and so causing the black bands to travel upwards at regular intervals. Several series of plates were exposed on this screen. The negatives are, in my opinion, equally as good in every way when the shutter was used close to the lens as when the shutter was placed next to the plate, with the advantage that there was very little distortion when the shutter was close to the lens, while it was very marked when close to the plate. After trying the shutter several times with the three-inch opening the opening was reduced to one inch, which gave the same results, only the distortion was greatly increased when the shutter was used close to the plate and not perceptible when used close to the lens, in this case the exposure being made in half the time of that with the shutter close to the plate.

Mr. W. BEDFORD said that the results might have been expected. When the shutter is close to the plate the object moves to a certain extent; when the shutter is close to the lens the object is moving all through the exposure; it is really a question whether preference be given to general movement or distortion.

Mr. EVERETT suggested that in photographing a cricket match the shutter might move in the same direction as the ball and traverse the plate quicker than the ball in the field; thus it might be possible to get an image of the ball and of the man being stumped, that is to say, get two effects upon one plate.

Mr. CLIFTON thought that the camera might be made to follow the object.

Mr. J. B. B. WELLINGTON said, in relation to the roller-blind shutter controversy, that it was good to have old gossips upset if they were proved not to be true.

Mr. WILLIAM ENGLAND tested shutters by means of a white string swinging pendulum fashion before a black velvet background.

Mr. KERR said that Mr. Haddon had proved that the lens had to be nearly a quarter uncovered before it gave any image at all, and this, perhaps, was why less movement was obtained with the shutter close to the plate than might have been expected.

Mr. S. G. B. WOLLASTON stated that under the system of experiments pursued the most horizontal lines must have had the longest exposure, and that was in favour of placing the roller shutter near the plate.

Mr. KERR had found an advantage in placing it next the lens, but did not know where the advantage came from.

Mr. A. COWAN said that the results before them certainly exhibited most distortion when the roller shutter had been placed next the plate.

Mr. BEDFORD thought the principle of the expanding diaphragm between the lenses to be better than that of roller shutters.

Mr. COWAN remarked that one of the best results before them had been obtained with the roller shutter close behind the lens.

Mr. KERR said that the plates of two makers had been used, but judgment should be formed from the average of the whole set of results.

Mr. COBB thought comparative experiments to be of little value unless all the plates came from the same batch.

Mr. W. H. HARRISON said that when mechanical apparatus was described to a public meeting either the apparatus should be produced or it should be described by means of diagrams on the blackboard, verbal descriptions alone were inefficient.

The CHAIRMAN then, by the aid of diagrams, argued that it made no difference whether the roller shutter were placed close behind the lens or next to the plate; he chose for his first illustration a pinhole aperture, and for his second a lens the full size of the plate; he further asserted that the principle which held good for these two extremes of aperture held good for all intermediate dimensions of aperture. Speaking with reference to the evidence of the photographs, he observed that these so-called practical proofs would require to be performed with extreme care, and repeatedly, before they could be supposed to controvert mathematical demonstration. In this particular case, he noted that

whilst one pair of photographs seemed to support Mr. Kerr's statement, another pair tended to contradict it. Various causes, such as changes of the light between the exposures, or a little difference in the sensitiveness of the plates used, would account for such differences in the result, without doing violence to arguments based on sound theory. As an instance of mistaken inference from a difference in two photographs, he referred to the pair now shown, taken of a wheel in motion, bearing a white card. It was argued that because the card was less sharply defined in one picture than in the other, there was more movement in the first than the second. On examining the photographs, however, it was evident that the want of sharpness existed not only at the ends of the card, where movement would show itself, but along the side which was travelling in one line, and that in fact that plate showed much blurring due to halation, and was probably thinner coated than the other. As to the idea that more light reached the plate when the shutter was close to the lens than when it was close to the plate, he thought that it might be proved to be fallacious in the following manner:—Let it be supposed that a plate of four inches was used, and a shutter with a four-inch opening travelling at a given rate, say four inches per second. Suppose also that the aperture of the lens was of the smallest, or take a pinhole instead. It would then be evident that with the shutter next the plate, each part of that plate would be exposed in succession for one second to the light coming through the pinhole. If the shutter were close to the pinhole, the whole of the plate would be exposed for one second to the light passing through the pinhole. The total light passed through would be the same in both cases, but in the first case part of the plate would be exposed earlier than the other part. That disposed of the proposition when the smallest possible stop was used; and by similar reasoning (which the speaker demonstrated upon the blackboard), it could be shown that the same result accrued when a lens of large aperture, supposed in the example chosen to be equal in size to the plate, was in use.

Mr. HADDON said that it would be different if a large plate were in the camera.

Mr. HADDON called attention to an aristotype print of the moon published in *Anthony's Bulletin*, of New York, copied from a negative taken by the aid of the Lick telescope; he believed it to be the best photograph of the moon ever produced.

On Thursday evening, February 14, lantern views relating to Holland will be exhibited before the Association.

CAMERA CLUB.

On Thursday, January 31, Mr. GRAMHAM BALFOUR, M.A., read a paper entitled *Figure in Landscape and Genre* (this will appear in a future number). Mr. Francis Cobb occupied the chair. The lecturer treated chiefly of the limitation of subject imposed by the means used in photography in regard to the use of models in landscape and in figure work.

A note from Mr. Lake Price upon the subject was read, and also a few words from a letter sent by Mr. H. P. Robinson.

A slight discussion followed, and the proceedings terminated by a very hearty vote of thanks to Mr. Balfour for his able paper.

After the meeting some apparatus by Messrs. Broughton were exhibited. Thursday, February 14, will be a members' lantern evening.

NORTH LONDON PHOTOGRAPHIC SOCIETY.

An ordinary meeting was held on February 5 at Myddelton Hall, Islington, — Mr. J. Traill Taylor, President, in the chair.

Rev. E. Healy showed a lens fitted with an Iris diaphragm by Mr. Newman; there was a slight catch to indicate each of the marked stops.

Mr. F. W. Hart showed a series of excellent photographs taken by his flash lamp, one 15 x 12 print being of a building taken at night, the flash sixty feet distant.

This was a lantern evening, and numerous excellent slides were shown.

The exhibition of members' work has been postponed from February 19, which will now be an ordinary meeting, to March 5.

CROYDON MICROSCOPICAL AND NATURAL HISTORY CLUB.

The ordinary monthly meeting of the Photographic Section of the above Club was held at the Public Hall, Croydon, on the 1st instant, — Mr. E. Straker in the chair.

Mr. BELLAMITH gave a demonstration of the Eastman Company's stripping film and transferotype processes.

McKellen's camera and the Eastman Company's "Kodak" were exhibited. A series of lantern slides from Kodak negatives taken in Italy showed the value of this apparatus for touring purposes.

During the evening Messrs. Watson's new camera was exhibited by the Hon. Secretary. Its design, particularly in the improvements shown in mechanical details, elicited the admiration of all present.

Much interest was aroused by the exhibition of the Scriptor Company's lantern slide camera, lent by Mr. George Smith, the ingenious arrangement by which a long extension can be obtained, and the compactness and convenience of the instrument, met with general approval.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

At the ordinary fortnightly meeting of the above Society, held at the Institute, Buxley, Friday, January 25, Mr. Pringle in the chair, the minutes of the previous meeting having been read and passed, Mr. Sanderson was elected a member.

Mr. Drusser showed a new album by the Eastman Company and some prints on Fry's paper which had been developed with hydroquinone.

Mr. Pringle showed a number of prints by the cold bath platinum process.

Mr. Crowe showed a transferotype print placed upon opal.

Mr. FENOLLS then gave an address upon *Practical Photography*, upon which a discussion thereon ensued.

The next meeting will be held February 8, at eight p.m.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting was held on Thursday, January 31, at the Royal Institution, Colquitt-street. Mr. R. J. Sayce, the retiring President, took the chair.

The minutes of the last meeting were read and confirmed.

Mr. SAYCE then, in a few words, introduced Mr. A. W. Beer, President-elect, who took the chair.

A hearty vote of thanks to the retiring officers and members of Council was then passed, on the motion of Rev. T. E. BANNER, seconded by Mr. WILLIAM SHARROCK.

Mr. SAYCE responded on their behalf.

Mr. Charles Adamson, Rev. F. A. Bartlett, M.A., Messrs. John Forshaw, jun., W. C. Hepworth, Fred M. D. Howard, J. K. Jackson, N. C. Jellico, Donald Matheson, H. B. Millar, Charles Pearson, Dr. H. B. Powell, M.D., and Mr. F. A. Schierwater, were elected members of the Association.

Mr. BEER then delivered his inaugural address. He said:—

During the twenty-five years of its existence great changes in the personal of the Association naturally occur, and the great bulk of our present members are amateurs of the latest and grandest epoch of our art-science. The perfection of the marvellous gelatine process has in these later days added enormously to our numbers, and it is to our recruits (if I may be permitted to use the term for want of a better) I would particularly address myself, relying upon the indulgence of those veterans in our midst with whom I have passed so many pleasant and profitable hours in the years that are gone. It is a truism to say a man cannot be in constant communication with others working for the same end without greatly increased knowledge and power to do better and more satisfactory work than before, and such, I take it, is our intention in banding ourselves together; as it will be at once admitted that productions amply satisfactory to the worker were he left to himself do not bring him that amount of self-congratulation when compared with the productions of more advanced students; but as he is the more likely to test the novelties that continually appear, so occasionally he finds something worth noting and communicates to others, and, consequently, both sides are benefited. While on this point let me say we detest an assumption of secrecy or secret processes, and particularly in a close society of amateurs meeting for mutual help, improvement, and encouragement, whose delight it has ever been to freely give to the photographic world in an inalienable manner their discoveries or improvements. I need not reiterate to you examples, you know them well. It cannot be commended that a man who is willing to draw from and learn everything that can be extracted from others then, labouring under the impression that he has discovered some little "wrinkle," carefully keeps it to himself; if he had been a careful student of photographic literature he would have long ago arrived at the conclusion that there was very little new under the sun, and the probability that his pet "dodge" had been published long ago. On the contrary, for the sake of our little commonwealth, should not each member take a delight in illustrating his particular achievements? Let one who is an adept in enlargements demonstrate his more successful methods, another lantern slides or stereoscopic work, or, again, some favourite method of mounting and finishing the work, and by so doing not only lighten the labours of our Secretary but also raise the value of the Association and increase its usefulness. Freely we have received our photographic knowledge, let us as freely give. Fascinating as is the pursuit of the photographic art-science, great as the pleasure derived from successful results, manifold as are the subjects waiting the combined action of the sun, the lens, and the sensitive plate, yet photography without a special end and aim, without a distinct object and purpose, is as a ship without rudder or a (hobly) horse without reins; yet in a great many cases the eager amateur, exposing his plates on anything that comes first, soon finds his new "fad" flat, stale, and unprofitable; he has made no special branch of photography his particular forte, or taken any individual class of subjects as his aim. In my own case I am absolutely certain such would have been the result, and at this time, when our ranks have been filled in so astonishing a manner, a word of advice and warning may not be amiss. If you desire your love for the art to be permanent and your interest in it continuous, take up some line or direction as a speciality, it does not much matter which you select so that you do choose one, either from the artistic side, as, for instance, some distinct class of landscape pictures, river studies, tree forms, flower pictures, broad landscapes, seascapes, clouds, or the more stable subjects, that may be more broadly defined as architectural, viz., picturesque exteriors and interiors of ancient churches, grand tombs and edifices, abbeys and castles, Norman doorways and arches, or even the despoiled black-and-white timber halls or colleges; studies of country life, always charming; of the itinerant vendors of novelties in the streets of our busy cities; old country inns, their signs and courtyards. On the other hand, there is the mechanical or scientific aspect—in plate making, the production of lantern slides or transparencies, improvement of the rapid shutter, and a host of other details. Once the interest is aroused the rest is easy; pictures or results are obtained that are of real value, due either to their intrinsic beauty or to the fact that it may be impossible to obtain them again. Localities are constantly changing, old landmarks are being ruthlessly swept away; towns take the place of villages, or an antique relic is in the line of some new railroad; churches are restored out of all knowledge, old manor-houses are destroyed by fire or rebuilt, and a thousand causes operate to effect changes innumerable; of what remains let us secure permanent pictorial records, educating our own minds and being of service to the community at large. How diversified are subjects that present themselves to the diligent searcher in this attractive field of study, and how ample the reward, when we find ourselves in the possession of charming pictures, the embodiment of our own fancies and the tribute to our taste, together with the knowledge that some little contribution is made to the store of general information, an addition that may be of permanent use to our fellows. Is it not a pleasure to be repaid for our exertions in hunting up some quaint, out-of-the-way relic of the past by finding that suddenly the photograph becomes of inestimable value as an unimpeachable testimony of what is gone, and that never can be replaced? Again, the amateur who adopts a class of subjects as a speciality must of necessity become more competent and proficient in that line of work than a mere dillitand worker, and so distinctly raise the general level of his work. For example, it will be admitted that the man who devotes a considerable amount of careful attention to photographing the interiors of our grand churches or ministers, either generally, as the naves, transepts, or choirs, or particularly, as the beautiful altar tombs, carved doorways, or clustered pillars, will produce work that astonishes the photographer who simply "takes" anything that comes first, and trusts in Providence (and his exposure tables) it will turn out all right—and, in present, exposure tables seem to me to be most fatal to

intelligent photography. Use them as "feeding bottles" while babies in the art, if you like, but when twelve months old cast them aside for ever. Certainly not by working out an equation, or amusing oneself with decimal fractions, are the finest pictures made. Use, if you will, a simple spectrometer for determining the value of the light in very dark corners, and for that purpose a scrap of silver sensitised paper is all you require. But I am straying from my subject. It must not be understood that the preceding remarks apply only to photographing the evidences of the past; they apply equally well to pictures of the shipping on our grand and majestic river, or in the docks that line its banks; to the tree-fringed meads of Cheshire, or the rocky glens and babbling streams of Wales beyond; to the busy life in our crowded streets, with the curious studies of the peripatetic, pavement-edge tradesman; applies with exactly the same force to the rendering of bold mountain forms, and the still, but beautiful, life to be found in groups of flowers or ferns. Pardon me if I finally reiterate the point of my remarks. Make some branch of photographic study particularly your own, in which you will do the truest, the finest, and the best work that can be done in that direction. Your art will then be to you a pleasure and a joy greater than it has ever been before, giving you new powers, and showing you fresh delights continually, making keen your appetite for other fields to conquer, quickening that artistic faculty possessed in some degree by all, proving an elevating occupation for spare hours all the year round, as in its multitudinous forms the art-photographic adapts itself to all tastes, all seasons, and almost all purposes. The first purchase of a camera and lens opens a door that comparatively few ever shut again, after they are initiated into the mysteries beyond. A new friend is made, ever willing to accompany you in your wanderings, never complaining of your choice of route, ready to stop when you stop, and journey when you journey, doing for you the work of a dozen artists with slow brush or pencil; a friend, whose company once enjoyed, you will never again wish to leave behind.

The Hon. Secretary exhibited Krugger's book camera, as introduced by Messrs. Marion.

The PRESIDENT drew attention to a circular of the Wirral "Footpaths Preservation Society," whose objects he recommended to the amateur photographers.

Mr. W. TOMKINSON then read a paper on *An Easter Trip to the South of France and Northern Italy*, which was illustrated by a large number of lantern slides from photographs taken on the trip.

The limelight lantern was under the able management of Mr. P. H. Phillips.

BATH PHOTOGRAPHIC SOCIETY.

A MEETING was held at 10, Quiet-street on the 30th ultimo, —Mr. W. Pamphrey, President, in the chair.

There was a large audience of ladies and gentlemen present to hear Mr. PHILIP BRAHAM, F.R.S., discourse on *Light: its Chemical Action, with especial reference to Photography*.

The lecturer said the question of photography nowadays was of such vast importance that no branch of industry failed to benefit by it. To-morrow, he said, would be the fiftieth anniversary of Fox Talbot's discovery of "photogenic drawing" being communicated to the Royal Society, and there were some present who could look back to the time when photographic processes were in their infancy. What is light? — what is electricity? he continued, is a question any one can easily ask. He could only reply, that light is motion, darkness is stillness. At present we regard light vibration in the all-pervading ether, a material in existence, and that ether has several attributes and qualities which can only be scientifically realised, because no one can say what is absolutely the case, but almost all experiments are explained by its means. Photography is not a science; it is an art. Music is not a science; it is an art. Painting is also an art. In science we must measure and weigh all our experiences; whereas with art, the canon of art is subject to change by time. Art cannot do without science, but science can do without art. He once heard a gentleman say that science was a bar to imagination, but that could not be substantiated, and only proved his ignorance of science and scientific workers. Light travels with a velocity of over 180,000 miles per second of time. The earth is only 24,000 miles in circumference — a small quantity in comparison. Electricity has been shown to travel at a similar velocity. Light travels in direct lines, and the experiments to be shown would demonstrate this; also in its passage through various media such as water, it is deflected in accordance with their surfaces. I have here, he continued, a means of throwing a powerful beam of light from an oxyhydrogen jet. In the path traversed by the rays we will interpose an empty sphere, and you see there is no difference. The light passes through, but when I fill the flask with water the beam is brought to a focus just beyond the sphere; if the liquid were denser, the focus would be nearer still. I have here a hollow glass vessel with plano-spherical surfaces; when I fill this cell with water there will appear a nearly perfect image upon the screen. I may also mention that a number of photographs have been taken with a liquid lens. You will notice that the spot, which in the case of the empty cell was at the top, is now at the bottom. We suppose there are a number of rays passing, and that these have become changed. What is the change? We put it down to refraction. Now what is refraction? I will interpose this glass lens, and place a star-pattern screen in front of the condenser, and by a suitable lens we get an image of the star through an empty cube upon the screen. Now I will fill this cube, or rather glass-sided vessel, with water, and replace the star with a line. No appreciable difference takes place, but if I turn the cube slightly the position of the image of the narrow slit is changed. Now we take a hollow prism, and as water is poured in the lines become shifted towards the base. The lines, too, are not only deflected, but coloured. A lens acts like an infinity of prisms, and is governed by the acuteness or otherwise of these prisms. The aim is to produce an achromatic lens. Here is a prism composed of three densities of glass: the lower a heavy lead glass, the middle portion of flint, and the upper of crown. This illustrates dispersion, and to the making of lenses the dispersion of one glass is counteracted by another. The refractive index known, and the amount of light dispersion, a lens almost perfectly achromatic can be constructed. Very few are absolutely perfect in the balancing of chemical and spherical aberration so as to produce an image of any object. It is also a question whether the human eye is perfectly achromatic. It is also a question of the chemical action of light. Light is the mainstay of all animated nature, as instanced in the interdependence of plants and animals; animals consuming the

oxygen of the air, and exhaling carbonic acid; vegetation consuming the carbonic acid, assimilating the carbon, and setting the oxygen free by the action of sunlight. In photography we have to deal with chemicals purely. Some have an idea that light is deoxidising in some cases, and oxidising in others. A few scientists think the effect to be electrical on the small particles or molecules acted upon. Here is a bulb filled with hydrogen and chlorine. It is possible the limelight may be too slow, so we will use magnesium to bring about a combination of the gases at present only mixed in the flask. [Experiment performed: explosion occurred.] Nitric acid decomposes in the light, giving off fumes of a yellow gas in the space above the liquid. Many a druggist has damaged his eyesight when withdrawing the stopper of such a bottle. Do they know that is due to light? In some experiments with Mr. Gatchouse I clearly demonstrated that the action was not on the acid but the vapour. No exposure to sunlight affects a tube entirely filled with HNO_3 , but if a space be left light soon renders it charged with gas above atmospheric pressure. What is chemical action? We only know that an effect is produced, and put it down to chemical action. Here are some tubes containing sulphide of calcium. When the light of burning magnesium is impinged thereon they become phosphorescent. We have now a number of streaks of light, but we cannot say a change of a chemical nature has been produced. Now, it is a fact that phosphorus is the least phosphorescent of any substance — it gives no light in the dark without oxygen and when there is slow combustion — yet the word phosphorus is derived from the supposed property of its bearing light. Is the effect chemical, or is it electrical? With regard to these phosphorescent tubes the particles may be electrically charged and go back to their original state by slow discharge. In some experiments with Mr. Friese Greene we not only got an effect by electricity, but also by magnetism. Photographic gelatine plates were placed between the poles of a powerful magnet, and on development showed a similar action to light, but also a spot of great intensity, which occurred not in the line joining the poles but considerably distant from them.

The CHAIRMAN, in thanking the lecturer for his able discourse and interesting series of experiments, said there remained plenty of work for those who were eager for research, especially in the direction of colour photography. That was the desideratum of the time. Opticians gave them forms of lenses almost perfect, but before colours could be obtained in the camera he imagined a complete revolution in the chemicals used would be necessary. The vote accorded, the Chairman made several announcements, and said he felt it his duty to state publicly that through the generosity of a member all expenses incidental to the formation of the Society, which were considerable, had been defrayed, therefore there was no leeway to make up.

A discussion upon the lecture followed, in which Messrs. Friese Greene (London), J. Dutton, J. A. R. Rudge, Philip Braham, the Chairman, and the Hon. Secretary took part, but no new points of interest were introduced.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

A MEETING of the above Association was held on the 4th instant, over seventy ladies and gentlemen being present.

The PRESIDENT (Henry Blandy, L.D.S. Edin.), in his opening remarks, referred to the courtesy of Professor Clowes, D.Sc., upon his consenting (by request of the Committee) to repeat his lecture, *A Visit to the Land of the Midnight Sun*, to the members of this Association. Mr. G. A. Ball had kindly consented to show the slides with his oxyhydrogen limelight, and being conversant with his ability as a lanternist we should know they would be put through in a masterly manner.

The lecturer, Professor CLOWES, was heartily received, and said that he hardly knew how to address them as a society of photographers, as he was in this art only a novice. But he would call their attention to the difficulty of obtaining good results from the deck of a vessel, and other unfavourable situations incident to a trip in Norway. His experience taught him to give preference to paper negatives, as being far more portable and not liable to break. He then proceeded to detail the incidents relative to the manners and customs of the people, and some fine views were thrown upon the screen, including three with the sun shining at midnight, the reflection on water being exceedingly fine.

SHEFFIELD CAMERA CLUB.

THE first annual dinner of this Club was held at the Freemasons' Hall on February 1. Dr. T. H. Morton, President, occupied the chair.

After the loyal toasts had been duly honoured, Mr. J. ELLINOR proposed "The Sheffield Camera Club," and coupled with it the name of the President. Although not a practical photographer, he held the art in high estimation, and was wishful to know the working of a society which had in view the advancement of photography.

Dr. T. H. MORTON, in responding, said:—

The Sheffield Camera Club, which has honoured me with the Presidential Chair, has not been established sufficiently long to render an audit of its accounts a difficult matter; but you will see by the short report that there is a balance in favour of the Society, and without wishing to be unduly complimentary, the work done during the past few months has been very satisfactory. I wish, in the remarks made this evening, to touch upon the present and future of this and kindred photographic societies; and let me notice in passing the extraordinary number of associations now existing, and probably if all the members were polled they would not represent a twentieth part of the devotees to our fascinating art. In 1878 the number of societies in the United Kingdom was fourteen, including a benevolent association; now, in 1889, we learn from the ALMANAC there are no less than seventy-five, and others are in process of formation. Similar institutions are springing up in India and the Colonies and other countries. The literature of photography has kept up with this general advance. The capabilities and object of photography are too well known for me to reiterate here, but I would hazard the question, What is a good typical photographic society? what its scope, aims, requirements? how does it fulfil the intention of its promoters and satisfy the members? In a few words allow me to answer, if only inadequately. In the first place, a society like this should be able to impart instruction, and that, at least, of such excellence that a member can intelligently follow

and take part in the debates. I assume this is a duty, especially when there are no means of education in the locality. It is surprising that the technical school here has not photography on its curriculum. The London City Guilds recognise its usefulness, and hold competitive examinations, conducted by Captain Abney, F.R.S.; but with the exception, I believe, of Professor Chapman Jones, at the Birkbeck Institute, Mr. Farmer, and one or two more, there are few actual teachers or schools of photography, although many are competent to teach, as C. H. Bothamley, Jerome Harrison, Lionel Clark, T. C. Heworth, Yvelantin Blanchard, and others. What would be the feeling of a person who had not attended a chemistry course who went to hear a paper on the allotropic modifications of carbon, oxygen, or boron, or to listen to a lively discussion on the morphology of mammalian vertebrae, unless he had some knowledge of anatomy or zoology. My impression is, that the decadence of many societies other than photographic is due to the want of timely preparative instruction. The new member attends one or two meetings, then leaves, a sadder but not a wiser man. Some will perhaps say, Photography is so easy now, anybody can pick it up. I heard a tourist saying to another (it was at Bettws-y-Coed, some years ago), "All you have to do is to clap your camera down here, and the thing is done!" and he gave the stone wall a smart hit with his stick. Perhaps he was describing the instantaneous process, which was the talk at that time. Well, I admit photography, the mechanical part, to a certain extent is easy, but is the uncapping a lens, using a standard developer, and taking a print on ready prepared paper from the negative, sufficient to satisfy the aspiration of an enthusiastic amateur. I trow not. He looks for art composition with a faithful portraiture of nature. He finds an extensive range of chemical and physical phenomena in the different methods of developments, the laws of optics and light in the lenses and exposures, and acquires by the aid of photography a true record of microscopic objects, astronomical data, and illustrations of travel, as well as health-giving exercises when in search for the beautiful. These sentiments require the fostering care of every society. I may say, in addition to elementary instruction, suitable subjects for discussion should be provided at regular intervals, and all members invited to contribute their share in the common stock. Laboratory experiments to be encouraged. Some societies are doing excellent work in this respect. Not is the social element to be ignored. Man is a sociable being, and thrives best when surrounded by a congenial sympathy. As regards exhibitions of photographs, now frequent and mostly competitive prizes being given, there can be little doubt that a medal or other reward is an incentive to produce good pictures; but when the highest awards are occasionally given for an indefinite period to the same work, it rather checks the production of new efforts. Again, the printing methods are now so various, one would expect the pictures to compete according to the process selected, say platinumotype with platinumotype, silver chloride with similar, and so on. When judging it ought to be known whether a picture is made direct from one negative or by means of two or three, or copying them and enlarging. Perhaps the Photographic Convention to be held this jubilee year of photography in London may arrive at some uniform system on these and other matters. The programme of our Club is not printed, but I trust the executive will be able to carry out the following items—a lantern entertainment; some elementary or practical class instruction, papers at each monthly meeting; and also the scheme suggested by Mr. Howarth, and which had worked well in the Birkbeck Society, viz., a photographic survey of the district, geological, historical, &c.—but the fulfilment rests in a great measure with the members. As the stability of any office depends upon the cohesion of its parties, so will the performance of this Club depend on the steady efficiency of each individual, and the united action of all. We can then hope to aid materially the progress of those arts and sciences to which photography is closely attached.

Mr. E. HOWARTH proposed "Local Scientific Societies," and spoke of the advantages astronomy had gained by the use of the camera.

Mr. FRANK HARRISON, M.R.C.S., President of Sheffield Microscopical Society, testified as to its utility in medicine and surgery.

Mr. LARBOYD, President of Sheffield Pharmaceutical and Chemical Society, also replied in an able speech.

Mr. WALTER NICHOLSON, artist, gave "The Health of the Council," and related some amusing incidents when meeting the camera in his excursions. He understood the difficulties in taking a landscape photograph, and considered the point of view one of the most important things. It should be very carefully considered. The difference of a few inches either made a picture or spoiled it. He was not very fond of instantaneous views of figures. Some persons were taken with leg or arm uplifted, and he felt that it gave a picture an ungainly appearance, or at least a feeling of unrest. He believed there was a great future for photography.

Mr. WINDEN replied on behalf of the Council.

Mr. NEWSON, M.P.S., in felicitous terms gave "The Visitors," and Rev. W. Seed and Mr. Neill responded.

During the evening recitations were most effectively given by Mr. Winden and Mr. Gilley. The musical part was well sustained by Messrs. F. Harrison, Grubbshaw, and Waddington.

The ordinary monthly meeting was held, and formal business transacted, before the dinner.

KEIGHLEY AND DISTRICT PHOTOGRAPHIC ASSOCIATION.

A WELL-ATTENDED meeting was held in the large Lecture Theatre of the Keighley Mechanics' Institute on Friday evening, January 18, to consider the advisability of forming a photographic association for the town and district. Mr. A. N. Kershaw presided.

In his opening remarks he said that the meeting had been called to test the feeling in regard to forming a photographic association. The time had come, now that they had upwards of one hundred photographers in the district, when they might very opportunely form such an association.

Mr. THOMAS HEAPS said that the Council of the Institute were very desirous of meeting any efforts which they as a body might be disposed to make. The exhibition which had been held in the Museum under the auspices of the Council of the Institute, to whom they were much indebted, was fast drawing to a close, and it was the feeling of all concerned that now was the time for taking action. Their Chairman and himself had sent out circulars calling the present meeting, and it was gratifying to him to see so many present. There were several reasons why they should form an association in connexion with that Institute. The first was the fact that the library already contained several good works on photography, and he had no hesitation in saying that any

proposition for the addition of new books which might be of general service to them as a body would be most favourably received by the Council. Then there was the reading room, which was supplied with photographic literature. There was also the old chemical laboratory that had been standing empty since the erection of the new wing, which was well adapted for their requirements in the shape of a dark room; and last, but not least, the small lecture theatre in which they could hold their meetings, lectures, &c.

After some little discussion, Messrs. A. Keighley, John William Darling, and Thomas Heaps were elected Committee *pro tem.*, to meet the Council of the Mechanics' Institute to arrange upon what terms they could be affiliated.

A general discussion now ensued, at the close of which it was decided to adjourn until Tuesday, January 29.

At the adjourned meeting on Tuesday, January 29, Mr. E. Myers presided.

The Committee *pro tem.* laid the terms of the Council of the Mechanics' Institute before the meeting, which were unanimously accepted.

It was moved, "That the thanks of the Keighley and District Photographic Association be accorded to the Council of the Mechanics' Institute for the valuable and instructive photographic exhibition recently held in connexion with the Institute." Carried.

It was proposed, "That the name of this society be 'The Keighley and District Photographic Association.'" Carried.

The following gentlemen were then elected officers:—President: Major Soglen, C.C., J.P.—Vice-Presidents: Mr. A. Keighley and Mr. Barton.—Committee: Messrs. A. H. Marriner, Ellis Myers, Thomas Heaps, A. Haggas, Preston, J. W. Thompson, E. R. Lee, and G. Smith.—Treasurer: Mr. E. Marriner.—Hon. Secretary: Mr. J. W. Darling, 3, Drake-street.

The meeting adjourned to Tuesday, February 19.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

ON Wednesday evening the members of this Society and their friends were entertained by Mr. ANSELMO PINHEIRO with an exhibition of Brazilian scenery photographically illustrated by limelight. All the subjects shown were taken by Mr. Pinheiro.

Mr. S. W. Allen occupied the chair, and the lantern was under the supervision of Mr. W. Windsor.

Correspondence.

Correspondents should never write on both sides of the paper.

FEBRUARY MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—A BIOGRAPHICAL DICTIONARY OF THE "BLACK ART."—THE SOCIETY INTENDS TO GIVE FÊTES TO FOREIGN PHOTOGRAPHERS DURING THE EXHIBITION.—POSITIVE PRINTING PAPER ON LINEN.—CATHEDRAL GREEN.—A DODGE BY M. LEMIRE.—POSITIVES ON SILVER CHLORIDE PLATES.—DEVELOPMENT BY HYDROQUINONE, REMARKS ON BY PROF. STEINING.

The monthly meeting of the Photographic Society of France took place on Friday evening last, the 1st instant, M. Davanne in the chair.

After reading the correspondence and voting the admission of new members, it was announced that M. Pector, a member of the Society, was compiling a new work in the form of a dictionary, in which will be given the biography of all persons who have invented or done anything for the advancement of the photographic art.

M. Ganthier-Villars, the indefatigable publisher of photographic literature, presented two of his new publications, the one treating of the value of land surveying by photography, the other on the way and means of obtaining a *souvenir* of a tour or voyage by obtaining views of the same. The Society appointed M. Londe to give a report on these books at the next meeting.

A discussion took place as to how the Photographic Society should act towards the foreign members of the proposed congress which is to take place during the exhibition. It is decided that a series of *fêtes* shall be given by the Society, to which will be invited, not only the members of the congress, but all photographers who will be on a visit to Paris at that time.

A number of very fine proofs from negatives taken from the Eiffel Tower were exhibited by Herr Mackenstain. These proofs received great attention, the foreground representing the iron skeleton of the tower, although no more than four yards distant from the operator was perfectly sharp, as well as the Trocadero and other objects in the distance. This lens was manufactured by Steinheil, focus five inches, diaphragm quarter of an inch.

M. Sengel and Dobler presented different kinds of positive paper upon a linen support. This idea is very good, and will render great service to architects, in that their drawings when reproduced by photography will no longer be liable to be torn and destroyed. These gentlemen not only prepare paper with the iron salts in this manner, but also for platina and silver chloride printing.

M. Balagny made a dissertation on the suppression of the red light in the dark room and replacing it by cathedral green, which he said was in every respect better, being at the same time as safe as the red. As this was recognised long ago in England, I need not dwell upon this subject except to say that with the exception of M. Balagny and a few of his intimate friends, cathedral green glass for the dark room has not met with the reception it deserves. A long discussion took place as to what colour was really the safest for the dark room. M. Franck said that he lighted up his factory of gelatino-bromide of silver plates with red glass,

doubled with a white pane of glass, which he had varnished with an ordinary negative varnish. This, in his opinion, acted far better than ground glass.

M. Balagny presented a negative, 27 x 33 centimetres, which he had obtained by a "single lens" manufactured by M. Balbrech, of Paris. The negative represented the Eiffel Tower, which has now attained the altitude of 237 metres above the level of the Seine. M. Balagny speaks very highly of the lens. He says it is very rapid. It is formed of three glasses—two crown and one of flint. Two of the glasses are in optical contact, the other is at a certain distance from the others. A good-sized diaphragm can be employed (half an inch), hence the rapidity.

M. Lumière, of Lyons, who was present, gave very good advice as to how it became easy to judge of the right moment to stop development. He said: "Suppose you have a lantern with a very large surface lighted up, it is impossible to judge if sufficient intensity has been attained or if all the half tones are visible. If you now allow a dark piece of paper having a hole no larger than a half-crown in its centre to fall over your lantern, you will be surprised and enchanted to perceive that you can see distinctly the value of your negative, because all the other rays emerging from the lantern are prevented from entering your eye."

MM. Marillier and Lobelet exhibited a rapid shutter manufactured by Mr. Werber. It consists of a U-shaped flange placed in the centre of the lens. When the legs of the U are before the glasses the rays are prevented from passing, when they are opposite the brass tube the image is delineated upon the sensitive surface. Great rapidity can be obtained by this system, and therefore it deserves attention. I think its motion might be described as the same action as the plug of a tap. When the plug is in a certain position the water rushes out, when in the opposite position the water is stopped, so with the rays of light.

M. Audra exhibited some very fine pictures on glass obtained by the silver chloride process. The image was developed by the hydroquinone developer and gave very good results. As for myself, I now prefer the hydroquinone developer to all the others, being cleaner, cheaper, and easier to manipulate when travelling than all the others. I am now on a tour through the south of France and Italy, carrying with me a whole-plate apparatus, with chemicals, &c., to develop the views taken during the day, and that in the bedroom of the different hotels. On an average I develop twenty-four plates every evening, and so can personally give the advice to try the formula given by me in one of my letters to THE BRITISH JOURNAL OF PHOTOGRAPHY, and all who do so will, as myself, offer thanks and songs of praise to the person who first thought of experimenting with hydroquinone as a developer.

Canine.

PROF. E. STEBBING.

ABSORBENT WOOL—CELLULOID.

To the Editor.

SIR,—In your impression of February 1, in your *Echoes* by "Junius," an inquiry is made where the absorbent wool is to be obtained. I note on the label of the packet that Messrs. Krohne & Sesemann, of 8, Duke-street, London, are the sole agents for Great Britain, and the packet is branded with a red cross. I understand that it is prepared by treating the cotton alternately by alkalis and acids. It is perfectly free from grease or soluble matter, and a tuft of it will sink instantly when placed in water. I have not tried it for filtering emulsion, for the simple reason that I find a properly prepared piece of charmois leather a more economical and perfect filter. The celluloid and magnesium compound referred to answers the purpose admirably. From later experiments with gun-cotton, of different degrees of explosiveness, dissolved in ether and alcohol I can make the material burn as rapidly as I desire, nor have I found the slightest difficulty in lighting celluloid of any thickness.—I am, yours, &c.,

A. L. HENDERSON.

Argyle Mansion, Brighton, February 3, 1889.

[Under the name of "Absorbent Cotton Wool," this material can be readily procured at nearly all the better class pharmaceutical establishments in London. Its price ranges from 1s. 6d. to 3s. per pound. It has been frequently employed in making pyroxyline, being so readily percolated by the acids.—Ed.]

PRUSSIAN STAINS.

To the Editor.

SIR,—In the ALMANAC you publish belonging to your paper you give a way of printing with the iron salts. I tried the one with ammonio-citrate of iron and potassium ferricyanide, and got my fingers stained blue all over, and I find that ammonia will take all the stain out. I thought possibly some of your readers might be in the same fix some day, and would be glad to know of a way to get rid of the stain.—I am, yours, &c.,

W. A. MEIGH.

Ash Hall, Stoke-upon-Trent, February 2, 1889.

HYDROQUINONE DEVELOPMENT.

To the Editor.

SIR,—For some time past I have been experimenting with hydroquinone as a developer, and am much pleased with the results obtained by using the formula published in your issue of November 23 by M. le Vicomte de la Tour de Pin. At the same time, I have tried this developer in

printing on bromide paper, and have found no difficulty in obtaining good prints. It is only necessary to wash well before fixing, and to use fresh hypo for each print. I cannot regard this as a disadvantage, compared with the great convenience of having the same developer for both negative and positive work. As an amateur, it seems to me preferable in many ways to the ferrous-oxalate process.—I am, yours, &c.,

Bournemouth, January 31, 1889.

JOHN J. MASON.

[The formula above referred to is as follows:—

Hydroquinone	1 part.
Sulphite of soda	2 parts.
Carbonate of soda	10 "
Water	67 "

—Ed.]

SORTING LANTERN SLIDES.

To the Editor.

SIR,—Having noticed various suggestions by members of the Photographic Societies and Clubs to overcome the difficulty and confusion of sorting the lantern slides after an exhibition—the suggestion of various coloured papers is good, but the tints would soon be exhausted, and without any settled arrangement as to choice of colour, there would still be a little confusion—my suggestion would accomplish a double purpose. It is now an understood thing that white paper on the top corner of the slide indicates that it should be placed downwards and face the condenser. Now, instead of the two pieces of white paper, numbers should be substituted, and the number should indicate the owner of the slide. A list should be made in the minute-book, thus:—No. 1. Mr. Cowan; No. 2. Mr. Wellington; and so on. After the exhibition the slides should be sorted, and the members ask for their particular numbers. Should any not be claimed then the list in the minute-book would show to whom they belonged. Now that there are so many societies and clubs it would be important that members belonging to different clubs should have the same number in each. The plan would be to start the first list at the Parent Society, the Secretary putting the names of the various exhibitors opposite a number, and forward a copy to the Photographic Club, who would enter the names opposite the corresponding numbers of those belonging to the two societies, adding the names of the members who are exhibitors, and then post it to the Camera Club for the same purpose, who would do the same thing and post it to the Photographic Association, and so on to all the London societies. When all this is arranged the secretaries would indicate to members their respective numbers. In order to keep the numbers clean it is advisable to place them under the cover glass. Now, Mr. Editor, should you approve of these suggestions, your position in one of the most active and prominent of the various societies may induce you to urge upon members the advantage of such a systematic arrangement.

I should be pleased to send sheets of numbers similar to the enclosed if the plan is adopted.—I am, yours, &c.,

F. YORK.

81, Lancaster-road, Notting-hill, W.

PSYCHIC PHOTOGRAPHY.

To the Editor.

SIR,—I have been reading the letters on this subject with much interest, as at one time I was trying experiments in this interesting study. I cannot see why it is impossible or incredible. The photographic plate may, with a long exposure, be able to receive an impression which the retina of the eye is not sufficiently susceptible to perceive. I took up the study with the aid of a professional medium, who at one time I believed to be honest, but I tried to leave no door open for imposition, and never allowed him, to my knowledge, to touch the plates before or after exposure, nor to have anything to say to their development; the plates were 5 x 4 slow Britannia, and were taken in my sitting-room with an exposure of about 25 to 28 seconds. I purchased the plates myself, and they were never out of my possession, and if they have been tampered with, I cannot understand how or when, unless the medium introduced at some time or another a box of plates which he had previously tampered with and sealed up to pass as a box fresh from the maker's hands. I shall be happy to leave some plates at your office for your inspection, and see if you think they are double exposures, or if you can account for the result in any way. I can simply state positively that they were taken by myself in my sitting-room, by daylight, with no one present but the person to be photographed, myself, and the professional medium. In some cases—not always—the plates are very poor specimens of photography, as I was just beginning; but, nevertheless, I would allow no one to have anything to do with them or touch them, so as to reduce to a minimum all chance of my being imposed upon. The figures are not recognisable by myself or any one who has seen them.—I am, yours, &c.,

W. A.

[This correspondent encloses his card as a voucher for his *bond fides*. We shall be glad to be afforded an opportunity of inspecting the plates.—Ed.]

MIDLAND COUNTIES' EXHIBITION.

To the Editor.

SIR,—By a clerical error the dates connected with the above exhibition were wrongly given in the advertisement of last week's issue. As it may

mislead, I ask the favour of correcting them. The actual date of the exhibition is from February 25 to March 2; and last for receiving exhibits, February 22. Thanking you in anticipation.—I am, yours, &c.,
47, Hagley-road, Birmingham. WALTER D. WELFORD, Hon Sec.

COPYING PAINTINGS.

To the Editor.

SIR,—Mr. Dunmore needlessly protracts this already tiresome discussion by putting forward another of his peculiar arguments—quite futile in itself—to prove what I already conceded to him. When he stated that “glycerine and water is the mixture advocated,” I replied frankly, “I accept his statement.” What more should any sensible man want? In order to prove that when glycerine is prescribed it means glycerine and water, he writes, “It is a very usual mode of expression to say that such-and-such a negative is developed with pyro or ferrous oxalate—now here common sense comes in” (Does it? I don’t see it. Having been previously absent, if it comes in now, it only comes in with the water diluted down to nothing—say, water, one ounce; glycerine, *quant. suff.*; common sense, *nil.*), “and suggests that the pyro or ferrous oxalate should be used with water, and not rubbed on the film *per se.*” Seeing that the said solution could not possibly be made without water, the illustration bears no analogy whatever to the use of glycerine, which, being a liquid in itself, does not entail the addition of any water, and in nine cases out of ten is used without it. If an instruction is thus given, say, “Fix with hypo or cyanide,” it involves the absolute necessity of water, which is a *sine qua non*; no one but a lunatic would rub the dry crystals on to a film or print, as that would simply mean instant destruction; but either glycerine *per se.*, or glycerine and water, may be smeared over a “painting brought to be copied” at the option of the destroyer. If I go to a chemist’s shop and ask for a few ounces of glycerine, I get it *per se.*—if he is a honest man—I don’t get glycerine and water. No! I don’t see where the common sense has come in.

He goes on to say, “May I ask ‘Pictor’ if he has ever himself seen an oil painting damaged or destroyed by the application of glycerine *per se.* or diluted?” Considering that not many weeks have elapsed since the cool promulgation of these pernicious instructions, as to the best mode of tampering with oil paintings entrusted to photographers to be copied, it is not reasonable to expect that I should already either have seen or heard of any injurious results from their adoption. I had never previously heard that paintings should, as a matter of course, be exposed to such risks, if it suited the purpose of the photographer so to tamper with them, and I was utterly amazed when I read of these things. Hence I deemed it my duty, immediately afterwards, as an experienced painter of pictures, to utter a strong protest and warning against such dangerous proceedings.

I may here describe an experiment which I performed a few weeks since. Two or three years ago I bought at auction a lot, consisting of an engraving and two old oil paintings; I bought the lot for the sake of the engraving. The oil paintings were of no value—mere lumber; one of them I destroyed last summer for the sake of the wood in the stretcher, which I used to boil my studio kettle. The other had a sketch pinned on until I finished it a month ago. The old painting was about twenty inches by sixteen, and it occurred to me before burning to use it up for experiment on the subject of this discussion. I cut it from the stretcher, and divided it by drawing white chalk lines centrally on the length and breadth, leaving an inch of neutral ground between the four sections. In a warm studio I applied to No. 1 section pure water, to No. 2 glycerine and water in equal parts, to No. 3 glycerine only, to No. 4 heavy imperial stout, in each case adding a few drops of a weak solution of oxgall, and using a distinct piece of sponge for each. Within fifteen minutes the stout was nearly dry, the water dry in patches, the glycerine and water dry only at edges of cracks, and the glycerine quite moist all over. On examining the back I found that the water had penetrated the most rapidly and spread the most extensively; the stout least of all. I renewed the applications every fifteen minutes for an hour, “keeping it moist.” I then left the picture to its fate for twenty-four hours; result—the water was quite dry, but had accomplished the greatest disintegration, and caused the paint to blister and scale off easily at the edges of the cracks; the stout was quite dry, having merely acted as a weak cement, leaving no ill effects beyond brown discolouration of the surface, which was easily cleaned off by a damp sponge and dry cloth, the slight blistering having subsided; the glycerine and the glycerine and water remained quite damp at the back all over their sections, and had even united across the neutral space, thus ensuring that permanent damp which leads to final destruction. The painting was of no value; if it had been of great value, any one of these empirical applications, except, perhaps, the stout, would have completely destroyed it.—I am, yours, &c., PICTOR.

[This subject, especially in regard to its “mutual admonition” aspect, has now received sufficient attention; and as “Pictor” has in his previous letter signified his intention of declining further altercation with “Free Lance,” we here close the discussion.—ED.]

PHOTOGRAPHING IN NORWAY.

To the Editor.

SIR,—Having in contemplation a photographic trip to Norway during the coming summer, I should be obliged if you, or any of your readers,

could give me any information as to whether there are any facilities in that country for sending on parcels of plates in advance to await one’s arrival at any given place. For example, intending in the first instance to land at Bergen, could parcels of plates be sent forward from thence by the steamers plying on the Hardanger and Sogne Fiords, “to be left till called for,” say, at any of the steamboat landing stages? If so, I should be glad if the proper way of addressing such parcels in Norwegian could be furnished to—Yours, &c., ALIQUIS.

[Pending the publication of a series of articles on photography in Norway, which we have in type, we have to request the favour of an answer to this query from any of our readers who have lately been touring in that country.—ED.]

MONEY PRIZES VERSUS MEDALS.

To the Editor.

SIR,—I think the time has come when one may ask for some expression of feeling among photographers generally as to the desirability of giving money prizes in place of the time-honoured medals? With money entrance and money prizes we shall soon find our way into the sporting arena.—I am, yours, &c., F. C. LAMBERT.

Cambridge, February 4, 1889.

Answers to Correspondents.

J. T.—Received.

J. W. RAMSDEN (Leeds), sends us an adapter for lantern slides, for which we thank him.

H. G.—You can register your design by sending a photograph of it, together with 1s. 6d., to our publishers.

EAGLE.—The only modern work published is a series of articles which appeared in this JOURNAL in the summer of 1883.

J. C.—If you suffer from the fumes of ammonia in the developer, better substitute a fixed alkali such as carbonate of soda.

A. J. CORRIE wishes to know if it is true that in an enlarged photograph the gradations of light and shade are never right.—Reply: This is not the case.

E. HOPKINS.—In order to ascertain whether the water is at fault better try one print with distilled. You might also try a little hypochlorite of potash in the developer.

JOHN HERRON.—Much depends upon the lighting of the studio. You may try from one to six seconds, no stop being employed. It is impossible to convey a more definite idea.

C. TRUSCOTT.—Send them to any auction mart in a town with many photographers.—In London, Stevens, of Covent Garden, makes a speciality of such, and fair prices are realised when the articles are in sound condition.

L. W.—To obviate the fog in your platina prints, try the system that was recommended by Mr. H. M. Hastings, which consists in developing with carbonate of potash solution to which a mere trace of hypochlorite of potash has been added.

JAMES WILSON & Co.—The best arrangements for your enlarging camera will be to place it level on a table and fix a mirror outside the window. This is hinged at the bottom and kept in position by a cord; it can thus readily be adjusted to the desired angle.

J. W. D.—We do not think you can purchase the lecture you require. If it is on the early history of photography, Hunt’s *Manual*, Jabez Hughes’s *Manual*, Harrison’s *History of Photography*, and the early numbers of this JOURNAL, will supply information from which a lecture can be compiled.

A. C. says: “At present I am occasionally using ready-sensitised paper. May I ask if paper thus prepared is considered as permanent in its results as that sensitised in the usual way by the photographer himself? I do not recollect having seen any article bearing on this subject.”—In reply: Yes.

FLORENCE says: “I saw some photographic magic lantern slides coloured the other day; can you tell me how they are done?”—We cannot tell, unless, like you, we saw them done; but copious instructions on the subject were published towards the close of our volume for 1866, to which we refer you.

THOS. W. MARSTERS asks: “If A brings to B a negative to print half a dozen copies, and while in the care of B the negative gets broken (not spoiled, but cracked), so that only vignettes can be got from it, to what extent is B liable to owner of negative?”—In reply: This is a matter on which we invite opinions.

ACCOUNTANT.—The probability is that if you had placed your collodion negatives in paper envelopes before stowing them away, instead of placing them in plate boxes, no cracks would have been formed. Before we can advise as to the possibility of their restoration, we would require to see a sample one, which may be of an average type.

ED. GORRINGE.—The influence of stops upon a lens, so far as concerns exposure, is this—that if you employ one having a certain aperture, say one inch, and it requires two seconds to obtain a good negative, an exposure of eight seconds, or four times the duration, will be required with a stop half the diameter of the previous one, and so on in the same proportion for whatever size you may employ.

W. G. G. inquires: “1. Have the new iris diaphragms any great or decided advantage over the Waterhouse? 2. Will rectilinear lenses take landscapes (pure) as well as single view lenses? 3. Can you tell me a suitable way of blacking the inside of cameras, dark slides, &c.?”—In reply: 1. They possess this great advantage, viz., that being attached to the mount they are not liable to get lost. 2. Yes, if they are so corrected as to give no flare spot. 3. Spirit varnish containing lampblack.

ONE WHO WAS THERE.—The mistake in our contemporary arose, without doubt, from his attempting the difficult feat of reporting a meeting before it took place. Captain Abney was unavoidably absent from the meeting.

HERRBERT WELSHORD writes:—"Will you kindly give me the name and address of any firm from whom I can obtain the necessary materials for working the 'dusting on' process; also the name of any pamphlet or work upon the subject." Mr. John Wenge, 11A, Berners-street, Oxford-street, bestowed a great deal of attention on this process some time ago, and issued a pamphlet devoted to it, together with a price list of the special materials required. Please yourself in communication with him.

A. W. S. writes:—"Is there any dye or substance which will give an intense solution of yellow in cold water or spirit? If so, where can it be obtained? Yellow only gives a pale solution in cold water. Can a spirit varnish other than collodion be dyed with bright crimson which will not turn violet or dark red when dry? I have tried sandarac, mastic, shellac, &c. Why not try dragon's blood or roseine, which to alcohol imparts a strong red? A good yellow is obtained by shaking up turmeric or saffron in alcohol."

AMATEUR (Cornwall). Our correspondent has been reading some articles, or papers, which appeared many years ago relative to the preservative action of collodion when applied as a varnish to silver prints; which, he said, was then spoken of in its favour, but as he has not seen any reference to this of late years, he inquires if it has failed in producing the effect desired and intended. We reply that so far from collodion protecting the picture, it rather favoured its fading; at any rate, a protracted experience with it showed that no advantage was attained by its employment. Hence it was discontinued.

MELANIE writes:—"Being desirous of learning photo-mechanical printing, with a view of adding that branch to my present business, I would feel obliged if you would kindly give me, through the medium of your columns, some hints as to the way I should set about it; or could you refer me to any books on the subject, and where I could procure the necessary material to make a start?"—The only work published in English on this subject, of which we are aware, is that by W. T. Wilkinson, published by England Brothers. Articles on this subject are appearing in this JOURNAL at the present time.

CH. KENNEDY states:—"I have been making experiments with sensitive papers prepared by floating paper upon bromide of potash, and then upon silver nitrate, and then washing away the free nitrate. I have tried developing after exposure with ferrous oxalate well restrained, but results are not A1. Would gallic acid do better? I cannot get good white, as the paper seems so subject to general fog."—We have seen prints with good whites and vigorous blacks which were obtained in the manner indicated, but the paper was sized with a strong solution of gelatine. A very slight excess of bromide will tend to cleanliness.

S. SWALLEY writes:—"1. I have had the misfortune to crack a valuable negative, part of the film being broken, which shows when printed from, mostly in the sky portion. Could not the print be touched up with something?—2. If I made a paper negative would the result be equal to the original?—3. My print washer has rusted where the holes are bored, and some prints have rusty spots. What can you suggest concerning this?"—In reply: 1. By covering the negative with two thicknesses of tissue paper, slightly separated, a print may be obtained in which the crack will not appear.—2. Yes, if properly managed.—3. Why not protect the prints by coating in the vicinity of the holes with a suitable varnish?

G. F. S. has made a quantity of gelatine emulsion, with which he has coated all the plates which he intends using at present; he is loath to throw it away as it is so excellent, and afraid to keep it on account of probable decomposition. He writes to ask if we can recommend any antiseptic by which it can be preserved in good working order until he arrives at Sydney, whither he intends proceeding.—Let him adopt a method that was patented by Mr. Kennett many years ago, which consisted in pouring the emulsion into a large, flat porcelain dish to only a very slight depth, and then drying it to thorough desiccation. This pellicle is then cut up in small pieces and stored in light-tight packages, in which state it will keep good for years. All that remains to fit it for use is to dissolve it in warm water.

RECEIVED.—L. J.; The Elf; G. W. Atkin; G. A. Ure; R. Von Dix; Mug; O. M. These and others in our next.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, February 13, will be on *Lenses*.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The annual general meeting will be held on Tuesday next, February 12, at eight p.m., at the Gallery, 5A, Pall Mall East. Paper by Mr. J. W. Swan, F.C.S., *Hydroquinone as a Developer*.

THE celebrated picture *Nana* was the subject of legal proceedings at Edinburgh on Tuesday. It was stated in court that the profits of exhibiting the picture were nearly 7000*l*. Artists and art critics may draw their own inferences from the fact—and moralists also.

MIDLAND EXHIBITION.—We have received the rules and regulations under which pictures are accepted for this Exhibition, to be held in the Fine Art Galleries, 26, Corporation-street, Birmingham, and remain open from February 25 to March 2. There will be quite a number of medals awarded.

FROM an advertisement in another column, it will be seen that Mr. Cobb, of Woolwich, has severed his connexion with the firm of Mayfield, Cobb, & Co., and has, in conjunction with Mr. F. A. Bridge, of Dalston, organized the firm of Cobb & Bridge, for the manufacture of the "Woolwich" plates. Their factory will be at Woolwich. We wish the new firm every prosperity.

CAMERA CLUB NOTICES.—Thursday, February 14, eight p.m., Lantern evening; members are requested to bring slides. Thursday, February 21, five p.m., Annual general meeting.

YORK FINE ART AND INDUSTRIAL EXHIBITION.—It has been decided to hold a fine art, ecclesiastical, educational, and industrial exhibition at York, in the buildings and grounds of the Fine Art and Industrial Institution, from June to October, 1889. It is intended that the Exhibition shall be of a superior character, especially in respect to the quality of the exhibits, and every effort will be made on the part of the management to exclude such articles as are not strictly appropriate to the objects of, or which might tend to lower the tone of, the Exhibition. Diplomas of honour, diplomas for gold and silver medals, and diplomas will be awarded by competent jurors or experts to such exhibitors in each department or section as may be deemed entitled thereto. The jurors or experts will be empowered to award medals in addition to the diplomas should they deem the exhibit of sufficient merit. The Fine Arts Section will form an important part of the Exhibition, and will be large and representative, including a very valuable collection of oil paintings by the old and modern masters, water-colour drawings, etchings, engravings, statuary, photographs, &c.

AMERICAN PIRACIES.—The *Globe* of Wednesday evening is "hot and heavy" on American piracy—artistic, literary, and photographic. It says:—"A glaring instance of this practice of filching occurs in the new number of *Wilson's Photographic Magazine*, published at New York. The frontispiece is a reproduction of Mr. Luke Fildes' well-known picture, *A Flower Girl*; but the artist's signature is smudged and scratched almost to the point of unrecognisability. In the body of the magazine are two columns descriptive of this frontispiece, under the heading, 'Our Picture,' but there is no reference whatever either to the artist or to the owner of the picture. There is plenty of stuff about Burnet's *Essays* and 'this beautiful photogravure print printed in that rich, warm tone, loved so much by artists,' and the editor even asks his amateur friends to try their hands at photographing the print, and to send him the results; but of the artist who dreamed and agonised and painted the picture, not a word. Mr. Du Maurier, like most other people, suffers somewhat from American enterprise (to give it a gentle name). We saw the other day at the studio at New Grove House a little book—little, but most impudent, which had found its way to England. It was published in America at the number of cents that are equivalent to a shilling, and contained nothing more or less than reproductions of Mr. Du Maurier's *Punch* sketches, with jokes attached. The preface consisted of a skilful analysis of the artist's work, but it was all cribbed from the author of *Daisy Miller*."

THE DUBLIN EXPLOSION.—We are not yet in a position to say definitely how Mr. Bewley lost his life by the explosion of the gas bottle alluded to in our last issue, whether it was by an explosion proper or by the bursting of the bottle by the pressure of the gas inside. Pending an authoritative statement relative to this, we give the following account from the *Freeman's Journal*:—"On Monday a terrible explosion occurred in the city, the result of which was the killing in an instant of a merchant who occupied an extremely high position in commercial circles in the city, and whose name was known and respected all through the country. The victim of the horrible catastrophe was Mr. Thomas Bewley, the senior partner of Messrs. Bewley, Webb, and Co., shipbuilders and manufacturers. The firm has, it appears, a patent for the manufacture of hydrogen gas—a very dangerous explosive—which was used principally for lighting country mansions, and it was the custom of the deceased, Mr. Thomas Bewley, to keep this gas stored in his office at the East Wall. On Monday evening, between four and five o'clock, the unfortunate gentleman was seen by some of his employees removing one of the iron bottles containing this gas from the drawing office to the shop adjoining, where he left it in a place of safety. He was then observed to go back for another, and when he had reached the top of the stairs between the two rooms on his return a fearful explosion took place, causing the utmost consternation and alarm amongst those on the premises, and rendering them for a short time utterly unable to understand what had happened. When the confusion had somewhat abated the awful nature of the occurrence was seen. Mr. Bewley was found lying at the top of the staircase horribly disfigured and mangled, and quite dead. His left arm and portion of his side and face had been blown away, and his body was otherwise gashed and torn in a most fearful manner. The damage done to the offices was very great, the windows and ceiling being completely shattered, and everything around was smashed and broken. Over the walls and portions of the ceiling which remained flesh and blood were spattered in a ghastly and sickening manner, while in the adjoining room was found, some time after the explosion, a hand torn and bloody. Part of the iron bottle which had contained the gas was subsequently picked up in the yard a considerable distance away. The deceased's brother, Mr. John Bewley, who was on the premises when the explosion took place, at once telephoned to Dr. Moore, Fitzwilliam-square, asking him to go immediately to the works. The doctor drove down without a moment's delay, but he saw on arrival that his services could be of no possible use, and pronounced life extinct. Superintendent Toole and Inspector Molloy, of the Dublin Metropolitan Police, arrived soon after, and placed some constables in charge of the body, which was left in the office. The deceased, who was about forty-six years of age, resided at St. Helen's, Avoca-avenue, Blackrock. He was connected for many years with the city of Dublin, and was known and honoured for his business integrity and tact, and his untimely death will certainly be heard of throughout the city and by all who knew him with keen regret."

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1502. Vol. XXXVI.—FEBRUARY 15, 1889.

THE DUBLIN GAS EXPLOSION.

It is quite easy to understand why much disquiet should prevail among photographers in consequence of the bursting or exploding of the gas cylinder, and of which a full account will be found on another page.

Gas cylinders are only of comparatively recent introduction, and their convenience is such as to have rendered them very popular among all users of oxygen or the limelight. Their absolute safety has always been accepted as beyond cavil, and thus while in the very heyday of their prosperity a cloud has been interposed between them and the public.

Fortunately, there is no occasion for the slightest feeling of alarm; the evidence tendered at the inquest sets the matter entirely at rest. The explosion occurred under circumstances as easy to understand as would that of a vessel filled with gunpowder were a lighted match applied. It was simply owing to a misadventure or blunder, and the nature of which was known to the party concerned. When oxygen and hydrogen are kept in separate vessels they are absolutely and entirely safe, but when mixed they form a violent explosive. This comprehends the whole matter.

We are quite at one with those who, when tendering their evidence at the inquest, suggested the desirableness of rendering it penal to place oxygen in a hydrogen bottle, or *vice versa*—that is, to do this commercially. For scientific or experimental purposes it would never do to interpose restrictions of this nature.

If this be done, and it be insisted upon that two well-marked contrasting colours be selected for the two classes of gas bottle—such as blue and red, or black and white—then the most timorous may use them with a feeling of the most perfect safety.

COMBINATION ENLARGEMENTS.

It would take up too much space if we were, in a single article, to attempt to describe all the different ways by which two or more small negatives may be used to produce one enlarged picture, therefore we shall confine ourselves to a description of one method by which it can be successfully accomplished.

Supposing it is decided to introduce, say, a group of figures taken instantaneously on a quarter-plate negative into an enlargement from a 5×4 , or larger size, landscape negative, the work may be successfully carried out by a method based on that introduced many years ago by Mr. T. Edge for double printing.

In the first place, the figures negative must be dealt with, the figures being carefully stopped out by neatly painting round them for about the eighth of an inch with black varnish. The remainder of the negative is then covered with opaque paper, so that if it were printed from in this state the figures only would appear on a purely white background. This done, the landscape negative must now be taken in hand, and have small pieces of gum paper fixed on its two sides, and on the top and bottom, to indicate the amount of subject it is desirable to include in the finished picture. This negative is now put into the enlarging lantern, and the image projected on to a piece of very stout cardboard the size the picture is to be—let us say 18×15 inches. The cardboard should be adjusted and fixed in the following manner:—Two small French nails are driven into the board of the easel for it to rest upon, while a third one is driven at the right hand side to serve as a guide, against which it is placed. A couple of drawing pins at the top will hold it securely in position. Now it is manifest that the cardboard can be removed and replaced in exactly the same position as often as may be required, so, of course, could any other rigid substance the same size.

The image is next arranged to size and focussed, a bold pencil mark being made exactly where each of the four strips of gum paper are shown. The object of this will be seen hereafter. The image being in focus, the place at which the figures should be introduced is determined upon. They are then roughly sketched on the cardboard the size required. The landscape negative is now removed from the lantern, and the figure one inserted in its place, the size and position of the figures being made to coincide with the pencil sketch when the image is sharply focussed.

A piece of bromide paper, 18×15 inches, is next attached to a piece of glass the same size, by means of a few touches of indiarubber solution on the back. The lens is now capped and the cardboard removed from the easel, and the bromide paper fixed in its place, care being taken that the side of the glass is placed in contact with the register nail. The exposure is then made, and the lens capped with a piece of yellow glass, which, while protecting the image from further action, allows it to be distinctly seen. Of course, if the picture were developed at this stage it would have the figures only with a plain white background. We have now to protect the already exposed portion while the exposure is made for the landscape. This we do by painting it over, while *in situ*, with an opaque pigment—Indian ink for example. This is simple done by tracing over the image as projected through the yellow screen.

The bromide paper and its glass are now removed and placed in the dark, and the cardboard again placed in position. The figure negative is next taken from the lantern, the landscape one introduced, and the size of the image adjusted to its original proportions, known by the gum papers on the negative coinciding with the pencil marks on the cardboard. The lens is then capped and the sensitive paper again made to take the place of the card, the precaution being taken that the side of the plate is pressed close to the guide nail. The second exposure is then made. All that now remains is to wash off the colour with water, assisted by a pledget of cotton wool, develop, and fix the picture in the ordinary manner. And, if the work be neatly executed, the juncture of the two negatives will not be perceptible.

In our first two or three essays the Indian ink was removed completely by the cotton wool, but in some subsequent ones, when using a second sample of paper, a slight stain was left on the surface, but this did not interfere with the development; and in the clearing, fixing, and washing, it disappeared entirely.

There are other methods by which the first exposed image can be protected while the second is impressed. Here is one. After the figure image is focussed, take a small piece of bromide paper and expose it and then develop. This picture need not be fixed, only washed and dried. The figures are then cut out neatly, by a pair of scissors or a sharp-pointed knife, and used as a shield instead of the pigment. It may be attached to the paper with a touch or two of indiarubber solution. The indiarubber can be easily removed, when the paper is separated, by gently rubbing with a clean finger.

When a number of enlargements of the same subject are required this plan of masking will be found more convenient than the painting, as the same figure-shield will serve any number of times. The reason why rubber solution is used as a cement is that it causes no expansion in the paper, and is easily removed without injury to the gelatine surface.

HYDROQUINONE AND SULPHUROUS ACID.

The question having been raised of the chemical purity of "permanent" hydroquinone, we have thought it worth while to re-examine the preparation, and now propose to say a few words on the subject of its alleged impurity.

In an appendix to Messrs. Zimmerman's letter a few weeks ago, we said that the sample in our possession was "perfectly" neutral, but the word should have been "practically," for although the ordinary tests for acidity would justify the use of the first term, it is well known that minute traces of sulphurous acid are not to be detected so readily as the stronger acids. Thus, with litmus paper, permanent hydroquinone not only gives no acid reaction, but if anything shows a tendency to restore the blue colour to the previously reddened test paper, although as a matter of fact it actually contains, or rather has mechanically mixed with it, a very minute trace of the acid in question.

The preparation to which the name "permanent" has been applied, differs from ordinary hydroquinone inasmuch as it possesses a clear and distinct yellow colour, whereas the substance in its strictest purity, though by no means in all commercial samples, is colourless. We expressed the opinion, upon first examining the yellow crystals, that the colour was derived in some way from sulphurous acid, though from the rough tests then applied we failed to detect its presence.

Solutions of hydroquinone or of pyrogallie acid containing free sulphurous acid, or what practically amounts to the same thing, an acid sulphite, possess the distinctive yellow colour shown by the "permanent" crystals, though colourless crystals may be obtained from such a solution upon evaporation if but a comparatively small proportion of acid be present.

Upon receiving Messrs. Zimmerman's letter, mentioning the presence of sulphurous acid in permanent hydroquinone, we submitted the substance to more careful tests than we had previously done. A few of the crystals were heated upon platinum foil in order to see if any combined sulphites were present, but the volatilisation was complete, leaving but the faintest mark behind, and that rather a dimming of the luster of the metal than a stain or deposit. Here we may say that in this matter the incriminated crystals behaved better than the strictly pure, simply on account of the presence of the small trace of sulphurous acid that gives them their colour. When heated moderately, hydroquinone first of all fuses, and as the temperature is increased sublimates or volatilises, but from the well-known instability of the pure product a small portion of it is decomposed in the operation, leaving a faint brown or blackish stain, which the presence of sulphurous acid prevents.

If a few of the yellow crystals be fused at a gentle heat upon platinum foil, or in a porcelain dish, and again allowed to cool and solidify, the yellow colour will be found to have entirely disappeared, in consequence of the escape of the loosely combined sulphurous acid. A similar result is obtained by making a hot, strong, aqueous solution, which, upon cooling, will deposit perfectly colourless crystals of beautiful form.

We next tested the crystals quantitatively for sulphurous acid in the free state, and as the average of six trials obtained a result of a little over half a grain in one hundred grains of the crystals, that is to say, one half per cent. instead of "several per cents," as stated. This quantity of free acid represents the equivalent of about two grains of sodium sulphite, a proportion which it is scarcely necessary to say is of no use whatever as a preservative of the hydroquinone in solution; in fact, it may be accepted as powerless for either good or evil in that connexion. It is not, however, useless altogether, for though, as we have said, it is insufficient to exert any preservative action in the solution, and is perhaps equally without effect on the crystals, still, indirectly, it conduces to the purity and stability of the latter, as we shall show.

We have spoken of the fact of the yellow colouration of the solution of hydroquinone in the presence of sulphurous acid, and have stated that when only a moderate proportion of acid is present the crystals will be thrown down without colour; but if a comparatively large quantity of acid be present it is impossible in the process of crystallisation to get rid of the last traces, notwithstanding the nature of sulphurous acid. This, as most of our readers are aware, is, under ordinary conditions, a gaseous substance, very soluble in water and condensable into liquid form at a low temperature. Hydroquinone itself is only moderately soluble in water at the ordinary temperature, so that it is easy to understand how even if a hot solution be saturated with sulphurous acid gas the crystals on cooling will separate almost entirely free from acid, that which remains being only mechanically imprisoned in the mass of crystals. Further than this, when the crystals are separated from the mother liquor and dried, a large proportion of the acid still remaining will be given off with the aqueous vapour, so that the quantity finally remaining will be very small, as analysis actually shows. This last remnant may be got rid of

by recrystallisation, when by its extreme solubility it remains in the mother liquor after the less soluble hydroquinone has separated.

Now, although the proportion of acid contained in the crystals of permanent hydroquinone is both harmless and useless, the presence of the larger quantity of acid during the process of manufacture may be of the greatest value in preventing the decomposition of an always delicate substance. In fact, perhaps the most dangerous stage of the process is when the moist crystals are exposed to the atmosphere in drying, when oxidation proceeds far more rapidly than in solution. At that period the presence of sulphurous acid is of the utmost value in arresting oxidation and enabling the crystals to be advanced to the dry and comparatively stable condition without decomposition. If this result can be attained, and the great bulk of the useless acid liberated as the crystals dry, so as to leave a product that is practically pure, and by no test proved to be in any way inferior to the theoretically pure preparation, there seems to be little cause for complaint.

It has been said that the proportion of acid remaining in the yellow crystals is equivalent in one hundred grains to the SO_2 contained in about two grains of sodium sulphite. When it is borne in mind that in dissolving one hundred grains of hydroquinone for developing purposes a photographer at once adds of his own free will four hundred grains of sulphite, the extent of the injury likely to accrue from the presence of the smaller quantity may be partially estimated.

A NEAT and easy way of mounting photographs in an album is always a boon to the photographer, and it becomes doubly so when a means of interchange of the views is provided. Mr. Zschendorf, a clever photographer, who occupies professionally a high place among the aristocracy of bookbinders, has for some time been devoting his attention to the carrying out of an idea by which these objects can be effected. As a result, he has now produced an album, the leaves of which are fitted with a double hinge, and perforated at the edge to enable them to be fastened in their covers by a silk tape. By this means groups of photographs pertaining to one particular subject may be collated and secured at once in the binding, and their further removal or change can be readily effected. We understand that the albums are to be placed upon the market at very little more than the cost of the mounts themselves. It follows that with one cover one can have a large supply of mounted prints embracing a variety of subjects from which selections may be made to stock the album for any particular occasion. It is a good idea well carried out, and will not fail to be extensively adopted.

HOWEVER desirable it may be, we would not say it is at all probable that the present generation will see the aspirations of Mr. James Glaisher fulfilled. At the first annual dinner of the Society of which he has so long been the esteemed head, Mr. Glaisher suggested the desirability of having a great central hall of their own, and which would also answer for the meetings of the country and metropolitan societies. While such a home would be suitable and desirable for any one Association, it would scarcely answer in London, where the societies are somewhat localised and sprinkled all over the suburbs, some at a distance of several miles from any other society. It is scarcely likely that any of these bodies would care to sink their individuality, especially as regards locality, by leaving their homes and the place of present meetings in their vicinity, to come all the way from, say, Stroud Green, Holloway, Primrose Hill, &c., to a common centre of, perhaps, Charing Cross. As regards the Society's own requirements, there is no reason why Liverpool or Manchester should be allowed to occupy such high vantage ground over London.

MR. J. W. SWAN has set a good example in abbreviating a rather long term, which it is confidently believed will ere long take its place in our vernacular—we refer to hydroquinone—a word which photographers cannot be reasonably expected to give full utterance to every time they have occasion to speak of it. At the Photographic Society of Great Britain on Tuesday evening, Mr. Swan, when reading a paper on the subject, and with reference to the tendencies that photographers have to abbreviate long words, taking example by pyro for pyrogallie acid, hypo for hyposulphite of soda, proposes to abbreviate the name of the new developing agent to quinone, thus omitting the hydro as not being necessary.

It is perhaps premature to announce that at the next exhibition of the Photographic Society of Great Britain the system of awarding medals, suspended last year by way of experiment, will be resumed; but if we rightly interpret such expressions of opinion as were made relative to this at the annual meeting on Tuesday evening, such will most probably be the case. There are many among the ranks of photographers who covet possession of the Society's medal as being the highest honour that can be awarded, and its being withheld for one year proved the *raison d'être* of their ceasing to exhibit on the occasion. The motive may not be a very high one, but we have to do with existing facts. We are, however, inclined to be charitable, and to attribute the non-appearance of old-time exhibitors last year to the terribly inclement summer, which prevented many from being able to go out with a camera.

THE identity of light and electricity has often been guessed at; a perfect parallelism has at last been proved. By means of a, comparatively speaking, simple arrangement, Dr. Hertz, of Carlsruhe, has succeeded in intercepting the ether radiations brought about by an electric discharge, causing them to behave precisely as light radiations would. By means of a parabolic mirror he collected the radiations, by a second mirror he re-collected them to a focus; if the second mirror were rotated through a right angle it lost its converging power on this particular light—polarised it, in fact. He interposed screens, and proved the light to travel in straight lines approximately. The most marvellous power of the radiations is the transparency of various bodies to their motion. The closing of the door of a room was no obstacle—the rays passed through as light passes through glass. Finally, the rays were refracted like light through a prism.

As various "opaque" objects were transparent to these new rays, there was no need for a glass prism, fortunately; the one employed was made of pitch, and had sides of over a yard long. It was set in the path of the rays, and was found to deflect them about 22° out of their path.

THIS is a marvellous achievement, but the account is evidently thoroughly reliable, for two English observers at once set themselves to the task of repeating the experiments, which they did with success. They polarised the rays by reflection, and found sheets of glass to be practically opaque, owing to the magnitude of the vibratory waves causing an action similar to that producing "Newton's rings." The waves are calculated to be about two feet from crest to crest.

WE have on a former occasion alluded to the rumours which have been current as to American intentions in the direction of a large telescope, and form is now given to them by the definite statement that Congress is to be asked to vote two hundred and fifty thousand dollars for the purchase of a refractor of the same (five feet) diameter. We do not know how the estimate as to the cost—which, be it observed, is for the refractor only, no building being mentioned—has been obtained, but when we remember that the producing the glass slabs alone for the Lick instrument, "only" three feet in diameter, was the work of many years, some faint idea of the magnitude of the task of making a five-foot instrument may be obtained. It is open to doubt the feasibility of producing the glass slab alone.

ECHOES.

While accepting Mr. Guttenberg's explanation—so far as it goes—of his flash lamp alluded to in recent *Echoes*, I must remind him of the old saw about the man "who complies against his will;" and whether the apparatus or my description be "all moonshine," whether the "fearful and wonderful" character of the lamp properly belong to it or exist only in my imagination, I beg to announce that I am "of the same opinion still."

In an interesting paper on *Lantern Transparencies*, Mr. Abel Heywood, jun., refers to the method of toning given in a leading article in the *Journal* some weeks since by means of mercury followed by liver of sulphur. This is not as popular or as well known as the beautiful tones it gives should make it; a result probably due in part to the unpleasant character of the potassium sulphide, and partly to the fact of mercury being employed, which is popularly believed to lead to instability of tone.

Whether this be necessarily the case, when proper care is taken, with any form of mercury toning I do not intend to discuss here; but this I wish to say, namely, that of all kinds of photographic images with silver as the original basis, none, in my experience, approaches in permanency to that produced by toning with mercury followed by an alkaline sulphide. When properly washed between the various operations—a precaution necessary for the mere integrity of the picture, irrespective of permanency—a beautiful image is left, which is not only quite permanent under ordinary conditions, but absolutely resists most of the bleaching agents, such as chlorine and iodine, and certain of the chlorides and iodides, which instantly attack the ordinary image.

It is true the sulphides are not pleasant substances to use, nor are they permanent in their character; but there is nothing dangerous to health, as many suppose, in their employment. The danger used to arise, in the old wet-plate days, from the fumes of sulphuretted hydrogen impregnating the atmosphere of the dark room, with the result that plates were fogged, and even baths thrown out of order. But in the modern dark room little such danger exists, and the inconvenience is confined to the unpleasant olfactory sensation produced. A friend of mine, however, asserts that "you soon get quite to like it;" which may indeed be true enough if the improved tones be taken into consideration.

It is a fine, "crusted," old idea that, while for astronomical and telescope purposes the very perfection of optical glass and the highest possible workmanship are absolutely necessary, yet, comparatively speaking, for photographic objectives anything in the shape of "second quality" glass and any sort of manipulation or working will answer. Not so, however, says Mr. Edward Bausch, whose dictum will, I think, cause some little surprise in many quarters. "I have found," he says, "that any lack of perfection which is noticeable in an eyepiece is as pronounced in the camera; and I therefore claim and make this emphatic that a first-class photographic objective requires as much perfection as that in the telescope or microscope, and no work spent upon it to accomplish this result is lost."

Now, while standing out to the utmost for the greatest *needful* perfection in photographic objectives, I am bold enough to venture to differ from so high an authority, who speaks more perhaps from a scientific than from a practical point, as an optician rather than a photographer. I repeat that I am in favour of the greatest *needful* or desirable perfection in photographic lenses; but every one must be aware that a point is reached—far short of that in telescopic or microscopic work—at which higher perfection becomes so much refinement wasted, "and the work spent to accomplish this result" is undoubtedly lost.

To illustrate my meaning I need look no farther than to Mr. Bausch's allusion to the use of an eyepiece. In the case of the telescope and microscope the eyepiece is universally employed to secure the highest degree of magnification, and the most perfect resolution of the finest details of the object. When only the axial rays are utilized, or with lenses of narrow angles, no inconvenience arises from this; but apply an eyepiece to the image produced by the most "perfect" of photographic objectives, including an angle of, say, 46° to 53° , and I rather fancy that the unaided eye view will be preferred. In fact, the photographic image will under no circumstances bear the application of an eyepiece, at least to the extent necessary and usual with the telescope and microscope.

But presuming we have a photographic objective as theoretically perfect in construction and in working as any telescope lens, one, in fact, the image of which will pass the ordeal of the eyepiece, and show faultless definition even to the extreme marginal rays, what becomes of the microscopic definition when the image is viewed on the ground glass focussing screen, especially if the eyepiece be then used? What, again, about the faultless definition when rendered on a modern rapid gelatine film, the grain of which in many cases is painfully distinct even to the unassisted eye? Granted even a perfectly structureless negative film, where is the paper to be obtained with a sufficiently homogeneous surface to reproduce the original integrity of definition? I heard an eminent American amateur declare once: "I consider when I print a negative on paper I spoil it." In fact, the surroundings of photography or of photographs are incompatible with the highest perfection in working of the instruments.

A good workman will have the best possible tools for his purpose, and to secure that end will spare no cost. Technical excellence means the expenditure of cost in labour and material; but where the result is a degree of super-excellence that is really of no use to the workman, he would be foolish indeed to incur the additional outlay for the mere purpose of satisfying the conscience of the scientist who takes a not unnatural pride in his work.

JUNUS.

GAS EXPLOSION AT DUBLIN.

It is reassuring to the users of compressed gas in cylinders to know, as the result of the inquiry into the cause of the explosion at Dublin, that it was not due to over compression, but to a mixture of two gases in one vessel. This, as the merest tyro knows, would be dangerous whether in a bag, glass vessel, or cylinder, if sufficient quantity of hydrogen and oxygen were contained therein. All who use the limelight, or are interested in it, will feel grieved at the calamitous result of a disregard of one of the most ordinary cautions; and your readers will all, I am sure, join with me in expressing heartfelt sympathy with the relations and friends of the late Mr. Bewley who so unfortunately lost his life through his belief in his own judgment in opposition to practical proof of the dangerous nature of the contents of the cylinder.

As there is not the slightest doubt from the evidence adduced that the explosion was caused from ignition of two *mixed* gases, it naturally occurs to one what can be done to obviate a similar occurrence, and make a certainty of the safe use "of oxygen and hydrogen." *First* and foremost, the two gases must be kept *separate*, and to this end the vessels containing them should be distinctly marked. *Second*, a test must always be applied before using to see that each gas is in no way mixed. *Third*, the pressure exerted on the vessel must never be nearly equal to its bursting limit. *Fourth*, the pressure for the delivery of the gas must be sufficiently equal (or at any rate so great) that by no possible means can one gas be driven back into the other vessel.

Now, as regards the separate vessels, if they are cylinders (and by common consent the days of gas bags, at least in Great Britain, are numbered), if they are distinctly painted—oxygen, *black*; and hydrogen, or house gas, *red*—by no possible means, without gross carelessness, could one be used for the other, and if they were, the error would be soon discovered by the test now suggested. This test may be made in one or two ways, but on my representation of the importance of the subject, Dr. J. A. Fleming, Professor of Electrical Engineering in University College, London, has designed a little apparatus that any one can use in a few minutes and satisfy himself that he is working with pure or known gas. It consists of a little metal tank or open-top box, six inches high, and about one and a half inches wide and deep, having a second compartment about half the height and the same width and depth as the other. The long one is open at the top, and the short one is closed by a light indiarubber cap. An inlet tube, fitted with stopcock, passes from the outside of the larger compartment along the inside base and into the second compartment, while an outlet pipe, with stopcock and fine-drawn orifice, is fitted to the smaller compartment. Perforations are made in the side connecting the two chambers, so that when water is poured into the open end of the large chamber, it may find its level in the other; or when gas is allowed to pass into the second chamber, it shall displace the water in it and cause the water to pass through the perforation and rise in the first chamber. The test is applied by connecting the gas vessel with the inlet pipe (after first filling the vessel up with water until it reaches the top of the indiarubber-capped aperture, and turning off outlet stopcock), and then turning on the gas from cylinder, bag, or other

vessel. As soon as this is done the water will commence to rise in the open compartment, and when it reaches to within half an inch of the top, or when bubbles commence to rise, the gas is turned off again by the inlet stopcock, and from the vessel. Gas will now be in the second compartment instead of water, and if it is supposed to be oxygen a piece of brown paper can be lighted and blown out, then held at arm's length opposite the jet with small orifice, so that when the tap is turned on the gas blows on the glow. If it fans into a flame and continues to burn satisfactorily, it may be known to be pure oxygen, but if with small explosions, then the gas should not be used but be at once allowed to escape in the open air. Supposing it was the worst kind of mixture of gases for exploding, the only result would be a small explosion in the little compartment of the test apparatus, blowing off the indiarubber cap and spilling a little water. If the gas is hydrogen, or house gas, it should burn with a steady flame, just in the same way as the hydrogen does when turned on at the lantern jet; but if it is mixed it will snap or perhaps cause a small explosion, as previously described. In case of doubt the experiment should be repeated.

This little "test apparatus" is the subject of a patent, and will be sold by Mr. J. H. Steward, London; but the price will be very low, so that every one may be in a position to satisfy themselves and reassure the public at a moment's notice. It goes without saying that the vessel must be emptied before a different kind of gas is tested. As regards "the pressure of the gas on the vessel not being nearly equal to its bursting power," no one should use a steel or iron cylinder without it has first been marked as "tested," or a guarantee given of the number of pounds pressure to which it has been subjected before filling with gas.

The one that exploded at Mr. Bewley's office was, no doubt, iron, and having been filled to what the scientific experts considered well within its strength, there need be no anxiety about the improved steel cylinders as made for the last two years or so, which are tested hydraulically to one and a half tons pressure before any gas is put in them.

A great safeguard to the public is that all cylinders filled by Brin's Oxygen Company, and which can be sent through any of their many agents for the purpose, are tested in this way—the steel to pressure stated above, and iron to forty or sixty atmospheres, or about 900 pounds pressure to the square inch, and then filled to thirty or forty atmospheres. By this means no risk is run by the users of gas from compression, for those that are faulty burst harmlessly in the water when tried.

Then, as to the fourth consideration, "the prevention of mixing of gases through unequal pressure or a suckback." I consider the fact of there always being so much pressure behind in the cylinders is their great safeguard, and from the evidence that no harm came to the operator who first tried the cylinder containing mixed gases for lantern purposes, it would, in my opinion, never have exploded if attached to a lantern jet, for the user would have had indication of something being wrong before the explosion occurred, which really happened, I understand, in Ireland, and the cylinder was sent back to Mr. Bewley marked "mixed" gas. If Hearle's automatic small size regulators are used the pressure on both hydrogen and oxygen is absolutely the same, and a constant and uniform pressure kept up until the last foot of gas is used; and should one gas give out before the other there is no possibility of their mixing or entering the other regulator, for the springs exerting the pressure on the small bellows connected with the valve eccentric being alike, one cannot be raised by the other, and without it is raised the gas cannot enter the bellows, and consequently cannot enter the cylinder. This being so, the use of the limelight can be considered perfectly safe as long as ordinary precautions are taken. It may be interesting to mention as instance of the strength of the steel cylinders of best make, that their lowest bursting pressure is twenty-eight tons to the square inch, and the limit of elastic pressure (that is, before they begin to bulge or bend) eighteen tons. This, combined with the fact that they are tested to one and a half tons pressure before filling with gas, should allay any anxiety both on the part of the public and the operator as to their use.

G. R. BAKER.

COMPRESSED GAS IN CYLINDERS.

During the last seven or eight days I have received no less than a dozen letters from amateur lanternists in various parts of the country, and as many others have personally called upon me, all inquiring if I could give any opinion or explanation for the terrible and fatal explosion which occurred in Dublin on the 23rd of last month, and by which Mr. Bewley was "blown to pieces." Many of my friends and correspondents have adopted the use of compressed gas partly by my

advice, and some of them (and at the present time there may be others) are so greatly excited and "scared" as to declare they will never again use compressed gas. I feel, therefore, that something ought to be said on the subject.

Respecting the Dublin explosion, I have no information except that which has appeared in the newspapers, and from what I read, it was not in using the compressed gas that the explosion occurred. It seems, therefore, to be simply an excess of pressure for the cylinder in which it was contained, or, in other words, the cylinder was not strong enough to withstand the pressure to which it was subjected. If this be so—that is to say, if the published reports in the papers are correct—then neither hydrogen or oxygen have anything to do with it, so far as their explosive or dangerous (?) properties are concerned, for air compressed to the same pressure would have burst the cylinder just the same, and, in all probability, would have produced the same disaster (except, of course, the fire which subsequently occurred, but which was as nothing to the bursting of the cylinder).

But now that the "scare" is so universal, we may reasonably consider the importance of precautions for the future.

Compressed gas has recently become so popular that several firms are making and supplying high-pressure cylinders in iron and steel, and there exists a strong competition in price. This, in a matter where the quality (good or bad) cannot be detected by the purchaser, is highly conducive to the supply of inferior articles, and notwithstanding it is said that they are all tested to a pressure greatly in excess of that at which they are intended to be used, we have no proof that the "test" was a real and satisfactory one.

I have personally known cases in the testing of a steam boiler by hydraulic pressure where an inspector would insist upon, say, two hundred pounds per square inch being applied before delivery, but the boiler maker, considering the test too severe, has "doctored" the pressure gauge, and whilst satisfying the "inspector" that two hundred pounds per square inch was applied, as a matter of fact not more than 150 pounds was applied; and other instances have come under my personal experience, where, through defective appliances and not by intention, less than half the pressure indicated was really applied.

These facts (well known to engineers and scientists), and the seriousness of the case as manifested by the Dublin disaster, point to the fact that each cylinder should be subjected to a Government test (as in the case of gun barrels), and I should not think there were many who, when purchasing a cylinder of, say, three or four pounds in value, would object to pay a few shillings extra for a Government test, and stamped accordingly. Indeed, it is a matter that ought to be enforced, and I should be very pleased to hear of the President of the Manchester Photographic Society, Sir Henry E. Roscoe, M.P., bringing this subject before Parliament.

But apart from the liability to accidents through excessive pressure, there is another matter to consider which might prove even more serious, that of the mixing of the gases, i.e., hydrogen and oxygen, in the same cylinder. At the present time, these cylinders are to be had on hire by any one, and may be used by any one, and goodness only knows how "some people" use them. There is no distinction between the hydrogen cylinder and another containing oxygen, except perhaps an ordinary luggage label is tied to the neck of the hydrogen cylinder.

Now, what assurance have the general public that a cylinder which contained hydrogen, and was returned only part empty, is not refilled with oxygen, and vice versa? It may be the custom of the manufacturers of compressed gas to empty the returned cylinders before refilling; but suppose the custom be for once neglected by the workman employed! the result might be too fearful to contemplate. The fact is, as things exist at the present time, we are working in the dark, and our lives, and scores of other lives around us, are at the mercy of somebody else's carelessness or carelessness, and this ought not to be, for there is no necessity for it.

I take it that the manufacture and supply of compressed oxygen is almost exclusively in the hands of the Brin Oxygen Company, and this fact alone gives them the power to keep the supply of hydrogen in their own hands too. Well, then, if the Brin Oxygen Company would adopt some system by which the gas could not be filled in wrong cylinders, and rigidly take their stand at that, they would establish a confidence with the public which has never yet been enjoyed. First of all, they should refuse to fill cylinders that were not officially stamped, or of known manufacture; every hydrogen cylinder should be painted white, and the oxygen cylinders black; the words "hydrogen" might be painted in large black letters on the white cylinder, and "oxygen" in white letters on the black cylinder; but in addition to this, and best of all, the screw ends for the unions should differ in size—let us say one inch diameter for the oxygen, and one and a quarter inches diameter for the hydrogen. Then the plant

or machinery used in filling or compressing should be constructed for these sizes, and in other, thus making it impossible for a workman, however careless, to fill oxygen in a hydrogen cylinder, and *vice versa*.

This simple system might have been adopted at first, but it is not too late now, and the sooner it is done the better, and the sooner will public confidence be established.

There is no more danger in using compressed gas for limelight purposes than when taken from bags and pressure boards, indeed not so much. The danger lies in the gases becoming mixed in one cylinder, and the higher the pressure of gases so mixed the more danger there would be. Oxygen and hydrogen mixed in one bag and exploded would be a mild affair compared with the same gases exploded under a pressure of one hundred and twenty atmospheres, or about three thousand times the pressure usually contained in a bag; indeed, if a charge of gunpowder loosely placed in a paper bag were exploded, and a similar charge very tightly rammed up in an iron box and exploded, the comparison would be a mild one.

Then the matter is too serious to be passed over quietly.

There are scores of cases, even for home use, where during the present season the oil lamps of single lanterns have been put aside in favour of "blow-through" jets, and a cylinder of oxygen with coal gas taken from the house main has been highly appreciated, not only for the superior light obtained, but the absence of the objectionable smell caused by all oil lamps, more or less, greater convenience, less trouble in many ways, and, in my own opinion, quite as safe, *if the oxygen is pure*.

In conclusion, I hope this subject will receive the consideration due to it, and that the public may obtain the satisfaction at present required.

W. I. CHADWICK.

PHOTOGRAPHIC OBJECTIVES.*

FACTS AND FALLACIES REGARDING THEM.

There is one point which I have not yet touched, and which is of the utmost importance, and that is the sphericity of surfaces. To simply grind and polish a lens is exceedingly simple; to do so and obtain spherical surfaces is extremely difficult. Instead of being spherical, a surface may be and often consists of a series of elevations and depressions. They may be in the shape of rings, or may be confined to spots or radiate from the centre, in which way I have seen them as pronounced as the spokes in a wheel. Heat, even when moderate, when applied to a certain portion of the lens, causes the same effect. There are optical tests by which you can easily see the expansion of glass after the finger has been allowed to rest upon it for a moment. The same effect may be obtained by fixing the lens in the mounting.

I have often examined lenses which were so distorted by the pressure exerted on them in the mounting that it seemed almost impossible that they could form even a fair image. What is the effect when these conditions exist? First of all, there is a lack of sharpness over the plate and then depth of focus. An elevation on the lens will give a shorter focus for all those rays which fall upon it, because of its shorter radius than the focal point for the entire surface; whereas a depression will cause a longer focus, so that instead of all the rays combining in one point there are a series of focal points. When depth of focus is caused by reason of this fault, it is to be condemned, because it is at the sacrifice of definition, and any lens possessing it cannot be rated as good. Depth of focus when caused in this manner is one of the qualities which can be determined without comparative tests, and every lens purchased should be tested to this end. A good means to determine the proper correction of the surfaces is by the use of a diaphragm. Focus for a sharp image on the ground glass by means of a magnifier with a full opening of the lens, and note this point in the camera. Then rack out of focus and insert a diaphragm sufficiently large that the image can just be distinguished, and again focus by means of the magnifier. If the objective is perfectly corrected, this point will coincide with the first, and if not it is, as stated before, a serious fault, because there will be a different focus for each diaphragm.

Depth of focus and speed are incompatible, inasmuch as both qualities depend on the aperture of lenses, assuming, of course, a relatively large diaphragm and focal length. While the former decreases with the increase in the aperture, the latter increases. Depth of focus is, no doubt, a very desirable quality, but to obtain it in a legitimate way with high speed is simply impossible. In two lenses of similar construction, of the same diameter and focus, it will be exactly similar, and the ratio of depth will increase with the decrease of the diaphragm. In view lenses depth of focus can almost

* Concluded from page 56.

always be obtained by the use of diaphragms, and this is also true in objectives specially made for portraiture; but in these the same is obtained by placing two systems farther apart or varying the distance of the individual lenses, which means nothing more or less than the production of spherical aberration.

The extent of flatness of field and distortion in lenses are variable quantities, and, although depending to a certain extent on the diameter of lenses, exist to a greater or less degree in one or the other lens, according to the amount of skill and care of the optician. The tendency almost since the first use of lenses has been the increase of speed and consequent increase of aperture of lens, and although the advance has been and is slow to the uninitiated, it means an enormous amount of work to the optician. Every degree of increase represents a considerable outlay of mental and manual labour, and can only be maintained by correspondingly greater attention to the minutiae of work. Each individual reproduction is to him a source of pride, and he works with love and ardour over every step of his work. Outside of this, however, he is fully aware of the detrimental influence of imperfect work, and his ambition is not only to accomplish the highest result, but to maintain it after it has been reached. The actual work of grinding and polishing is comparatively trifling, as is shown in the cheaper form of lenses, where the cost of glass is just as high, but wherein the lenses are used whether good or bad, unless they have faults easily noticed. The time-consuming and worrying work is that of continually testing and correcting the lenses. When we remember that the best, although none too good, involves the amount of work I have endeavoured to portray, you will no doubt feel that the optician does not ask for much remuneration for it.

Now, as to the homogeneity of glass. A disc should be of the same consistency throughout. When it is not, it possesses either impurities or air bubbles, which are usually easily seen, or so-called striae—which are not so discernible, but of greater importance. These are caused by the unequal consistency of the glass or unequal annealing, and have a similar appearance to a glass of water when strong sugar water is poured into it and is not well mixed, or heated air as it rises from a stove or hot ground. All glass not specially made for optical purposes has them, and can be easily seen by looking through it edge-wise, even in the best plate. Of course no disc is used which shows them, or air bubbles, or impurities on a preliminary examination; they often appear before the lenses are completed, and work then ceases, but very often they cannot be detected until the lenses are finished. Air bubbles can easily be seen by any person, and when they exist the optician must judge whether they are sufficient to impair the saleability of a lens.

If, however, a man who has a reputation to guard permits it to pass—and I would add that it is as hurtful to his eye as to any person—then the purchaser should not be hasty to condemn it, for it then usually possesses merits which far outweigh this disadvantage. Take, for instance, an air bubble as large as a pin's head in an ordinary size lens. Its area is so infinitesimally small as compared with the area of the lens, that it is of no account whatever, and does not effect the lens in the least. Although it may sound strange, I would, for my part, select a lens containing an air bubble in preference to one without it, provided they were from one reliable firm.

Striae, however, which are difficult to detect, are positively injurious when existing to any extent, inasmuch as they refract the rays passing through them in different directions, thus preventing them from combining to form the image, and they sometimes may cause a false light. They often pervade an entire lens and occasionally can be seen with the naked eye, but as a rule not. An easy method of looking for the most glaring is as follows:—Unscrew the systems and examine each separately. Place one in the camera or on the table in an upright position, and back of it, at any distance, a lamp or gas jet. Look for the focal point by means of a white paper, and get the eye in the same position, which can be easily done after a little practice. The lens will be found brilliantly illuminated, and the striae will stand out as dark shadows. When a few small knife edge threads show, they are of little moment, but when in a circle of light there is a wavy appearance it is generally indicative of other striae which are injurious, but cannot be determined in this manner.

I have shown how some of the faults may be determined by almost any person, but others, such as definition, distortion, and amount of speed can only be judged by a comparative test or by a person of wide experience. Comparing a lens with one of known excellence is the only reliable manner, but then the following points, among which I recapitulate those already mentioned, should be observed. Determine coincidence of visual and chemical foci. Determine coincidence of ground glass and plate in plateholder. Use flat plates when ground glass is flat; if this is not flat, use plates corresponding with it. Determine spherical correction by means of diaphragms.

The two lenses should be for the same size plate, and of about the same aperture and focus. Lenses should always be tested first with full aperture or large stops of the size, as small stops correct spherical aberration in good lenses as well as poor ones. If desired, they can be done with small stops later on. Make comparisons under the same conditions of light. For spherical aberration and distortion, focus on printed matter or on a map fastened to a screen, and have the lens square with the objective and within two or three times the equivalent focus of the lenses, as they are then under the most strained conditions. For depth of focus use stationary objects which have thickness, or a view. Always focus the lens on the same point, and never make a comparison without the use of a magnifying glass for focussing as well as for examining the negatives. Last, but most important, make the comparison in the spirit of arriving at the truth, and do not permit your judgment to be biased or influenced by your feelings.

EDWARD BAUSCH.

SPHERICAL ABERRATION IN PHOTOGRAPHIC LENSES.

The following is a simple method by which the spherical aberration in photographic lenses may be measured. If I am addressing any photographers who are not conversant with optical terms, spherical aberration may be illustrated by focussing an object on the ground glass with a small diaphragm in the lens, such as $\frac{1}{8}$; on the diaphragm being removed, the ground glass will have to be racked nearer the lens, in order to bring the same object again in focus. The distance it is so racked is termed the longitudinal spherical aberration of the lens. In performing this experiment, a small object in the centre of the field should be chosen, and the result will be better seen if a circular patch of paper be stuck on the centre of the lens, when no stop is used. Spherical aberration must on no account be confused, as it often is, with curvature of image.

Longitudinal spherical aberration being the distance the ground glass must be moved to keep an object in focus when the centre or a marginal zone of a lens is used, a measure of this distance would be a measure of the longitudinal spherical aberration. It is, however, not easy to measure this distance, especially if it is small, with an ordinary camera without special apparatus. The following is a simple manner in which it may be accurately done with ordinary means:—

A small piece of printed matter is placed in front of the lens to be tested, at a distance equal to about ten times the equivalent focus of the lens. The image is now carefully focussed on the ground glass, the lens working with its full aperture (a focussing glass $\times 10$ should be used). The distance between the paper and the lens (optical centre, strictly; practically, the lens of a single and the diaphragm of a doublet) must be accurately measured. A small stop, say $\frac{1}{8}$, is placed in the lens; if the printed matter be now examined at the ground glass, it will probably appear not nearly as sharp as it was. In order to get the image as sharp as it was before, without disturbing the distance of the ground glass from the lens, the slip of printed matter will have to be brought nearer the lens. When the image is again precisely sharp, the new distance between the paper and the lens must be accurately measured. All that is now necessary is to refer the difference between these measures to the conjugate focus by the following formula:—

$$L = \frac{f^2 (d - d')}{d d'} \text{ where}$$

L is the longitudinal spherical aberration; f the equivalent focus of the lens; d the distance, less the equivalent focus of the lens, between the paper and the lens when the full aperture of the lens was used; d' the distance, less the equivalent focus of the lens, between the paper and the lens when the lens was stopped down.

Example: $f = 6$ inches. The distance between the printed matter and the lens in the first instance = 60 inches, and in the second = 45 inches.

$$d = 60 - 6 = 54$$

$$d' = 45 - 6 = 42$$

$$L = 36 \frac{(54 - 42)}{54 \times 42} = \frac{12}{63} = \frac{1}{5} \text{ inch nearly.}$$

Therefore an object which had been focussed with the full aperture, and photographed at $\frac{1}{5}$, would not be sharp on the plate with the above lens.

The effect of focussing with a large aperture and photographing with a small one is to draw the focus nearer the lens on the object side, and consequently to send it farther from the lens on the plate side.

Thus, if the object were a carved church door with a railing two or

three feet in front of it, the carved door being focussed with a large aperture and photographed with a small one, the railing would come out the sharper on the plate.

EDWARD M. NELSON.

COLLODIO-BROMIDE EMULSIONS.*

In the *Photographic Times* of September 4, 1885, Mr. Levy thus describes his method of working.

I will explain the manipulations in the way I think is the most practical, and by following them closely success will be certain; for fifty-four ounces of emulsion mix the following:—

A.

Bromide of cadmium	618 grains.
Alcohol (absolute)	18 ounces.
Iodide of ammonium	161 grains.
Cotton (Hance's cream)	586 "
Ether (concentrated)	27 ounces.

In another bottle:—

B.

Nitrate of silver	600 grains.
Alcohol	9 ounces.
Nitric acid	270 drops.
Distilled water	360 "

Pour A into B and leave exactly ten hours, then add ninety-nine grains of green chloride of copper.

The excellent flowing qualities of any emulsion, its sensitiveness, &c., I ascribe, first, to the minimum quantity of water I put into it, and also to the correct measurement and timing.

First, I would advise to weigh out the required quantity of bromide of cadmium, and then desiccate this in a porcelain capsule on a gentle heat. It will first soften and boil, and the heat must be applied so that the bubbles do not blow out any of it and change the quantity, however small the loss, as every particle is closely calculated. Then it will form in a lump (I forgot to say that during this evaporation the bromide should continually be stirred with a strip of glass, so as to prevent its adhering and consequent burning), when, by continuous stirring, it will granulate, and this should be pushed long enough until the granulation is fine enough and powdery, showing that all the dampness has gone. This powder, well scraped out of the capsule, is put into one half of the given quantity of alcohol and shaken until well dissolved. The iodide of ammonium is now added. This should be of a light yellow colour. When this is melted add to it the cotton and shake well, after which the ether is added and another good shaking given. This first operation in one of the bottles previously well cleaned. It is well to have the bottles about twice as large as necessary, as it allows better shaking, and, of course, mixing.

In the second bottle put the nitrate of silver and the water (which must be counted by actual drops, and not measured), the actual amount of which must dissolve the silver; but as it will not do it while cold, it must be gently heated until the required result, when the second half of the alcohol is added. On a small quantity the addition of the alcohol leaves the solution transparent, but on a larger quantity the silver is precipitated. This does not in any way affect the result. All of these manipulations may be performed in full daylight, but the subsequent ones must be done in the dark room.

After having well shaken the silver solution, add to this the collodion in small quantities of four drachms to an ounce at a time; shake very well at every new addition, until all is transferred. The emulsion is now almost finished, and should be shaken occasionally during ten hours (exactly, neither more nor less), when the chloride of copper is added, giving a thorough shaking again, so as to dissolve it well, and also for other reasons.

Before adding the chloride of copper it must be put in a capsule and well evaporated. This can be easily perceived by the colour, which must be thoroughly brown when fully dried. Contrary to the bromide, the chloride should and must be weighed after the drying process is gone through. I may add that the dried chloride will keep very well in that condition if placed in a well-closed glass stoppered bottle. If it gets green it must be again evaporated.

Filtering is now advisable through Japanese filtering paper or cotton when the emulsion is finished. The preservative composed is as follows (preservative for forty-four ounces):—

Tincture nux vomica	100 drachms.
" scilla	42 "
" cochineal	120 "
Honey	20 ounces.
Acetic acid	20 drachms.

Of the above take twenty-two drachms and add sixty-four ounces on water. After coating the plate, allow the film to set well, and the rinse in water before applying the preservative.

On reference of the above to Dr. Higgins, to whom, through a perfected formula, the honour of the commercial introduction of dry plates in this

* Condensed from page 89.

country is due, he endorses it as in the main correct, the time for the introduction of the nitric acid and its effect. A very important matter is, however, wanting, as also other details necessary to its successful making. These the Doctor has promised to give in a practical demonstration before our Society of the art of emulsion making to the utmost minutiae, so that any one with ease and certainty can make a reliable and satisfactory emulsion.

Dr. J. J. Higgins also gives me his formula for developing the above plates, as follows:—

Carbonate soda.....	4 pound.
Ammonium bromide	640 grains.
Honey	2 ounces.
Water	1 quart.

The above is strong for extra cases. When diluted one half it forms the usual normal developer. To half an ounce of the above add a mustard spoonful of dry pyro previous to applying to the plate.

It will be observed in these various formulae that considerable restrainer is added to prevent fogging, which is quite different in the case of the gelatine plate. If the alkali and pyro are poured on a collodion plate without containing a restrainer, the film will darken almost instantly. Very little practice is required to obtain excellent results, and I hope the reviving of this subject may lead to further improvements, especially when it is noticed that collodio-emulsions for ortho-chromatic work is being suggested.

F. C. BEACH.

THE CONSTRUCTION OF PHOTOGRAPHIC LENSES.*

LET US now retrace our steps. You will remember that refraction is due to the fact that the wave length of light is altered by passing from one medium into another of different density. This light, however, does not consist of one vibration but of a series of vibrations, each with a different wave length, and it is a fact proved by experiment, and accounted for by theory, that these vibrations have their wave lengths altered in passing from a rare into a denser medium in a different manner.

We have shown that it is possible to construct an optical system which will refract a bundle of parallel rays to a single point, but in doing so we have assumed that the light was caused by vibrations of the same length, namely, that it was of the same colour. The rays, however, have not the same wave length.

This defect, namely, that a bundle of white light entering a lens does not come to the one point owing to the fact that light of different colours is refracted to different extents, is called chromatic aberration, and the correction of this error is one of the most important of the optician's duties. The amount of the difference between the refraction of the extreme colours when passing through a glass is called the "dispersion" of that glass. Glasses can be made which have different refracting powers, and with the difference of the refracting power the dispersion generally varies. If the dispersion of these glasses were always in the same proportion to their refraction, it would be impossible to correct for this aberration, for suppose we have a convex lens which has a dispersion one-tenth that of its refracting power, by which I mean that if it brings the violet portion of a bundle of parallel rays to a point nine inches from the lens, it will bring the red portion to a point ten inches from the lens, and suppose we place a concave lens in front of this convex lens, which will give us exactly the same difference in the refraction of the different colours (but being concave it will be in an opposite direction), then, if the amount of the dispersion of this glass is also one-tenth of its refraction, we shall, in order to neutralise the dispersion of the convex lens, require a concave lens of exactly the same focus, and shall also neutralise the refracting power of the combined pair, and the compound lens no more acts as a lens, but as a parallel plate of glass.

It is found, however, that glasses can be made which have different degrees of dispersion in comparison with their refracting power. In general the more highly refractive glasses have a higher proportional dispersion. We might perhaps find, for instance, that a glass had a dispersion equal to one-fifth of its refraction, instead of one-tenth part.

If, then, we make our convex lens of a glass that has a dispersion only one-tenth of its refracting power, and make our concave lens from the glass which has the higher dispersion equal to one-fifth of its refraction, we shall find that the latter will only require to be half as powerful in order to correct the dispersion of the original lens, and although it will have neutralised by one-half the original refraction, there will still be left remaining a power equal to half that of the convex lens. Thus, for the correction of chromatic aberration, it is important to note that the proportional to the relative dispersion. If one glass has a dispersion of one-tenth of its refraction, and the second glass has a dispersion one-fifth of its refraction, and if we make a positive or magnifying lens out of the first glass, and a negative or diminishing lens out of the second glass, provided the first lens has a refracting power double that of the second, the chromatic aberration will be corrected, no matter what the shape of the lenses, and it is evident that by altering the curves of the lens, but always having the same balance between the two curves, either of the lenses may be made in many different shapes, and yet give the focus

required. Thus the correction for achromatism depends not upon the shape of the lens but on the foci of the two component lenses, while, as we saw before, the correction for spherical aberration depends not upon the foci lenses but upon their relative shapes. There is therefore no difficulty in correcting for both spherical and chromatic aberration in the same pair of lenses.

The formula, the conditions of which must be fulfilled in order to obtain an achromatic pair of lenses, is a simple one and runs as follows:—

FORMULA A.

$$\phi_1 = \frac{(\mu - 1)}{\Delta\mu} \quad \phi_2 = \frac{(\mu - 1)}{\Delta\mu} \quad \phi_2 = \frac{(\mu - 1)}{\Delta\mu} \quad \phi_2 = \frac{(\mu - 1)}{\Delta\mu}$$

When $\phi_1 \phi_2$ are the refracting powers of the two lenses, and—

$$\left(\frac{\mu - 1}{\Delta n} \right)_1 \left(\frac{\mu - 1}{\Delta n} \right)_2$$

the relative dispersions of the two glasses in use. Let us take an example where the relative dispersions in two glasses are 43.3 and 36 respectively, the equation then becomes—

$$\phi_1 = \frac{36}{43.3} \text{ or } \phi_1 = .87 \phi_2.$$

From this it will be seen that, by assuming the focus of one lens, we are able to find the focus that the correcting lens must have. I think it would be as well to mention that, owing to the fact that the dispersion of a glass is never proportional, the complete correction for achromatism is less simple than this would lead one to suppose, but for the purpose of illustration it is not at present necessary to further discuss this point. We saw that with a pair of lenses it was possible to correct for spherical aberration. The mathematical formula which must be satisfied in order to do so is by no means simple. I give it below without attempting to indicate the steps by which it is obtained. Any one interested in the matter will find it fully discussed in Herschel's *Light*.

FORMULA B.

$$O = \left\{ \begin{aligned} & \frac{\phi'}{\mu'} \left\{ (2 - 2\mu'^2 + \mu'^3) \rho'^2 + (\mu' + 2\mu'^2 - 2\mu'^3) \rho' \rho'' + \mu'^3 \rho''^2 \right\} \\ & + \frac{\phi''}{\mu''} \left\{ (2 - 2\mu''^2 + \mu''^3) \rho''^2 + (\mu'' + 2\mu''^2 - 2\mu''^3) \rho'' \rho''' + \mu''^3 \rho'''^2 \right\} \\ & - \frac{\phi' \phi''}{\mu' \mu''} \left\{ (4 + 3\mu'' - 3\mu'^2) \rho''' + (\mu'' + 2\mu'^2) \rho''' \right\} \\ & + \frac{\phi'^2 \phi''}{\mu'^2 \mu''} \left\{ 2 + 3\mu'' \right\} \end{aligned} \right\}$$

where

$\phi' \phi''$ = refracting powers of two lenses;
 $\mu' \mu''$ = refractive indices of the two glasses;
 $\rho' \rho''$ = curvatures of first lens;
 $\rho'' \rho'''$ = curvatures of second lens.

Suppose, now, we wish to make up a system of two lenses out of two given glasses, and to correct it for spherical and chromatic aberration by means of these formulae. We will assume the focus of one lens, and from formula A for achromatism we shall obtain the focus of the second lens. We therefore know $\phi' \phi''$ and $\mu' \mu''$. What, then, are the unknown quantities in formula B? The four curvatures of the two lenses $\rho' \rho'' \rho'' \rho'''$.

In the construction of photographic lenses we always endeavour to have as few reflecting surfaces as possible, in order that no large proportion of the light which enters a photographic lens may be reflected back again. Thus, in making an achromatic pair of lenses we endeavour to make one curve of each lens the same, and to cement the lenses together. That is to say, we make $\rho' = \rho''$. This considerably simplifies the equation (B), we have only three unknown quantities, and, moreover, we have from the following two equations connecting them:—

$$(\mu' - 1) (\rho' - \rho'') = \phi'. \quad (\mu'' - 1) (\rho'' - \rho''') = \phi_2.$$

Thus we can reduce our formula to a form where only one unknown quantity exists. It is true it is an equation of considerable complexity, but when we have inserted the known quantities it is merely a matter of arithmetic to simplify it. Now arises a point of some interest. The solution of this equation will give us the shape of the lens that must be made in order to obtain a compound lens free from both spherical and chromatic aberration, and a lens of a shape that will not satisfy this equation will not be accurately corrected. It would therefore appear that for any two given kinds of glass, the lens would have to be made of one particular shape and no other. But if we examine the expression in B more closely we shall find that when simplified out it becomes a quadratic equation, and that it has in general two roots—that is to say, with most kinds of glass two shapes of lenses can be made, each of which will give perfect correction for spherical and chromatic aberration.

There are glasses which, however, we generally avoid, whose refraction indices and dispersions are such that the roots of the equation are imaginary, and we find that with these glasses it is impossible to obtain

* Continued from page 89.

a system of this nature of any shape whatever that shall give a perfect correction for the aberrations. We shall find that in this case we must make lenses whose curves are not the same, which cannot therefore be cemented.

I have sketched the necessary shapes of the two forms of lens given by two kinds of glass which are in constant use, and it will be found that most of the glasses that have until recently been employed will give for their corrected lenses shapes that are more or less similar to the two forms figured.

Fig. 5

It is interesting to note that the form No. 2 is that generally employed for telescopes, as the curves are less sensitive to slight alterations, while the shape No. 1 is that which is employed for a large number of photographic objectives, on account of properties which this form of lens possesses that I shall have again to allude to. In order to make this point more clear, I have sketched a series of lenses all made of the same two glasses, all corrected for achromatism, but in which only one is corrected both for spherical as well as chromatic aberration.

There are many ways of combining the lenses so as to correct one or other of the aberrations, but, as we have seen, in general only two for correcting the two together.

Fig. 6.

SERIES OF ACHROMATIC COMBINATIONS SHOWING DIFFERENT DEGREES OF ABERRATION.

We have so far only considered that bundle of rays which passes through the centre of the lens, and forms the centre of the picture; and, as we have shown, it is necessary, in order that this portion of the picture should be sharp, that there should be no spherical or chromatic aberration. The question next arises as to what method is employed in order to obtain sharp pictures at the margin of the photographic plate; that is to say, by what means a bundle of rays passing through the lens obliquely may be brought to a single point.

Now, a good plan undoubtedly would be to make a globe of glass, and use a spherical plate, except that the achromatism would be difficult to correct, and it would be difficult to use different apertures or stops. For it is evident that a bundle of rays passing through a globe would be affected

in an exactly similar manner, whether they passed straight through or at an angle. But the globe is impracticable; it has been tried, and has been discarded for many reasons.

Another plan which would work equally well is, that the complete lens should be two portions of a hollow globe, of which the surfaces are concentric—thus. Here, also, you will observe the oblique rays would pass through a similar set of surfaces to the central rays, and although a certain alteration would take place, we may say that practically the oblique rays would be refracted to a single point, provided central rays were refracted to one point.

Now, what are the ways in which opticians have hitherto corrected for the aberration of the oblique rays, which is called astigmatism? The globular lens was tried, and found unserviceable, and though hitherto the concentric lens has been an impossibility, we have reason to believe that in the future this form of lens will be made. The method of correcting for this astigmatism has been by making the lens as nearly as possible of the concentric form. If it were quite concentric the lens could not, with our usual glass, be made of the required refraction, so that we have been obliged to make lenses which are far from being concentric, but which, being made in the form of as deep meniscuses as we can make, somewhat approach the concentric form, and thus improve, but in no way annihilate, the astigmatism.

Let us suppose we are anxious to make a lens to cover a plate that subtends an angle of, say, 30° to 40°, and that shall have an aperture one-eighth of the focus. Suppose the focus of the lens be ten inches, then the bundle of rays that enters the lens from any point of the object must be ten-eighths, or one and a quarter inches. The lens cannot be smaller, therefore, than one and a quarter inches, and it is found for other reasons that it must be at least one and a half inches. The deepest curve we can conveniently make of that diameter is, say, nine-tenths of an inch, or thereabouts, and this limits the convexity of the meniscus that can be used. Well, we know that in order to correct astigmatism we require the lenses to be as deep as possible, and as nearly parallel as possible, so we decide to have our lenses of such curves that the deepest is about nine-tenths of an inch. We decide to have a pair of symmetrical lenses in order to have no distortion, and that they shall be placed in a position to give as nearly as possible the form of a hollow sphere. Now comes the point—What glass shall be used? We observed before that with every two kinds of glass the lenses could only be made of two shapes. Thus, we must look through our glasses to see which pair will best give us this deep meniscus form. We shall find that for a lens of the type I have mentioned, the glasses known as light and heavy flint combined together will give the nearest approximation to the shape required. That is to say, in order to be able to make a lens with these very deep curves we must use two glasses, whose refractive indices and dispersions are unusually close together, otherwise the adequate corrections cannot be obtained. For a lens with a larger aperture than one-eighth of its focus the lenses must be larger; it is then no longer possible to employ so deep a curve as nine-tenths of an inch, as it would be more than a hemisphere and could not be made, and the curves must of necessity be of a flatter form. We must again look through the kinds of glass at our disposal, and we shall find that glasses with a greater difference between their refractive indices and dispersion must be selected.

This will have, I hope, indicated very roughly and briefly some of the general defects of a simple lens, which we, as opticians, endeavour to correct. For portrait lenses we devote ourselves beyond everything to the correction of the spherical and chromatic aberrations of the central rays, because large apertures are necessary in order to make the lenses rapid, and the larger the aperture the more the defects in the aberration show up. That is to say, in portrait lenses we devote ourselves to the central definition of the lens. In rapid and wide-angle doublets, although the central aberrations must be carefully attended to, the corrections for astigmatism and distortion are the most important. Again, with single landscape lenses a certain amount of distortion is tolerated in order to obtain better marginal definition. In order to describe all the different details of construction, it would not require a single paper but a series, and I doubt if any but opticians would be interested. I have been unable to touch this evening on many points of special interest.

The flare-spot and its causes and modifications in various kinds of lenses would be a subject that, to be fully treated, would require considerable time. Wherever light meets a polished surface of glass a portion of the light is refracted and a portion is reflected, and thus with every lens a certain amount of light enters the camera which has not passed straight through the lens, but has been reflected backwards and forwards from the various surfaces of the combination before entering the camera. The amount of this light is exceedingly small, compared with the body of light which passes through the lens, and if it is diffused over the whole of the photographic plate, it has no appreciable effect. It, however, sometimes happens in a carefully adjusted lens, more usually of the doublet form, that the greater portion of this light thrown into the camera by internal reflections is concentrated upon one part of the plate, and forms a patch of light called the flare-spot.

Another interesting point is the special chromatic correction which has to be made—owing to the irrationality of the spectrum—in order to make the focus coincident for the chemical and visual rays. In this connexion, you will no doubt expect me to speak of the new optical glass which has recently been made at Jena. I think it has sometimes been supposed

that the advantage that would be gained by the use of this glass for photographic objectives would be mainly due to the destruction of the secondary spectrum. I anticipate no improvement worth mentioning from this cause. Those who are familiar with that beautiful optical correction of a telescope object-glass, and who have compared it with the correction of the best photographic objectives which are purposely imperfectly corrected in that direction, will realise that the correction of the secondary spectrum is of very little consequence in the construction of photographic lenses. There are now being turned out from the glass factory at Jena over ninety kinds of glass, and some of these possess very remarkable qualities, such, that I think it not impossible that we may be able to make in the future a doublet lens that is absolutely concentric, and in which the covering power is thereby largely increased. There are many serious difficulties in the way, and although the firm of which I am a member have been for many months working in this direction, the investigations are not yet sufficiently complete for me to be able to give you any definite information as to their results.

I will not to-night discuss the much debated point as to whether it is legitimate to leave a lens more or less imperfectly corrected for aberration in order to obtain the so-called "depth of focus." All such points as these may appear to be of secondary importance, but they must nevertheless be carefully considered in the construction of photographic lenses.

In concluding this paper, I hope I may be excused if I make one or two remarks on the methods of constructing optical instruments. When the principle of achromatism was discovered, the achromatic telescope was made by Dolland largely from practical experiments. The achromatic microscope was worked out by Lister and others by practical methods, and even at the present time many things are done in practice which are not even known of by theoretical men. I believe I am correct in saying that there is no book which gives a correct representation of a high power microscopic object-glass, and most of the figures which are to be seen in books are entirely misleading.

There can be no doubt that in certain branches of optics the practical man formerly led the way, and it was only afterwards that his methods were theoretically explained. This naturally produced among opticians a certain contempt for theoretical work, while the theoretical men were somewhat sceptical of the rule of thumb mode of inquiry often employed by the instrument maker. Thus it comes to pass that we find in England, except in rare instances, very little combination of practical and theoretical men in the production of optical instruments. Practical men are realising that although the improvements that have in past years been made in optical instruments have been in a great measure due to the empirical method of inquiry, now that the science is more completely worked out, and the conditions have become less simple, the advances that will in future be made will undoubtedly be due more or less to theoretical research. Now we opticians are men of business, who have not only to make optical instruments, but also to make a living out of them, and have not so much time as we should like for theoretical work. What, then, is our annoyance when we find, on entering the study of the subject, that the books are now written, not that they may be of practical use, not that they may advance the science, but that the student may have simple formulae and dodges to pass examinations. The pure mathematician is apt to be so impressed with the necessity of having a formula that is of a pretty and symmetrical form and easy to cram for examinations, that he sometimes arranges his signs and terms in a manner such, that in order to make practical applications of the same the formula has to be entirely reconstructed. Is it not a disgrace to our literature that in optical text-books the thickness of a lens is generally neglected or merely mentioned as a corollary? It is only within the last year or so that any accessible English book has treated adequately of aberration since the time of Herschel. The investigation of oblique pencils is generally left almost untouched, and the question of signs is in a chaotic condition. If theoretical men will combine with us practical men by writing books by which we can educate ourselves in the direction we require, there are many improvements in optical instruments which, in the not distant future, we may hope to accomplish.

CONRAD BECK.

(Discussion in our next.)

THE LARGEST CAMERA IN THE WORLD.

[A Communication to the Photographic Society of Philadelphia.]

THE recent completion of the great Lick telescope, and the success which has attended its use for general astronomical purposes, have been subjects of interesting discussions, both among astronomers and mechanicians, and an examination of the photographic features of the instrument may not be without interest to photographers. Before entering into a description of the attachments of the telescope which are particularly devoted to photography, a brief general account of the instrument may be necessary in order to make clear the arrangement of the parts.

As the vital point in a camera is the lens, so the objective is the great point in a telescope, and the objective of the Lick telescope, the last and greatest work of the veteran Alvan Clark, is the first and most important part of the instrument. The clear diameter of the lens is thirty-six inches, and it is composed of two discs of crown and flint glass respectively, both discs being cast by Feil, of Paris, and ground and figured by Mr. Clark, at Cambridgeport, Mass.

The production of a satisfactory and homogenous disc of glass, free from waves and striæ of unequal density, is a most difficult matter, and in the case of the disc of crown glass a satisfactory casting was secured only after nineteen failures. The crown glass lens is a symmetrical double convex figure, both faces being worked to curves of 259.52 inches radius, and the double concave flint disc has its front face worked to a radius of 239.59 inches, and its back face is curved to a radius of 40,000 inches. The discs are not cemented, but are mounted six and a half inches apart, the combination having a focal length of 678 inches, or 56 feet 6 inches.

This lens, the largest in the world, is mounted in a tube of cast-iron and steel, the tube being four feet in diameter in the middle and tapering to three feet at the ends. This is mounted equatorially, and some idea of the weight and solidity of the parts may be obtained from the fact that the polar axis is a steel spindle ten feet long and twelve inches in diameter, and it alone weighs 2700 pounds. The weight carried by this axis is about 20,000 pounds, and in order to relieve the spindle as much as possible, a series of anti-friction rollers are placed just beyond the first bearing to take a portion of the weight.

The instrument is mounted on a hollow cast-iron column, built up in sections, the driving clock and regulator being placed in the column, and connected by electric control with a standard astronomical clock, and with the chronograph.

The control of the telescope in all its movements is effected by the numerous handles which are gathered around the eyepiece and upon the top of the column. The instrument is intended to be controlled by the observer and an assistant on the column, although for rapid movements in right ascension and declination help may be given by an assistant on the floor. The various handles and attachments for the use of the observer are mounted on a large ring around the eyepiece, which carries the handles for clamping the instrument or giving slow motion in right ascension or in declination, and also carries the reading microscope and finders, and a small sidereal clock. Electrical switches are also provided by which the driving clock can be started or stopped, and the illumination of the divided circles controlled.

It has been customary in large telescopes to provide a chair for the observer which followed the motion of the eye end of the instrument, but the inconveniences of this method increase with the size of the apparatus, and in the case of the Lick telescope it was decided to adopt the method proposed by Sir Howard Grubb, of making the entire floor of the dome rise and fall to bring it at all times within a convenient distance of the eyepiece. As this moveable floor is sixty-one and a half feet in diameter, and has a rise and fall of sixteen feet, the magnitude of the task is apparent. The motion of the floor is caused by four telescopic hydraulic rams operated by a differential valve provided with an indicator which may be read in the dark. A hole in the middle of the floor provides space for the column of the telescope and for a staircase, and the entire motion of the floor is accomplished upward in less than nine minutes, and downward in five minutes.

The great dome is also controlled by hydraulic power through the medium of an endless wire rope, and in this manner the unusually heavy parts are kept as completely in hand as in the case of smaller and lighter apparatus.

The most interesting part of the outfit to photographers lies in the accessory apparatus for use in celestial photography, and as the telescope when arranged for photography may be considered the largest camera in the world, some of its details in this direction are worthy of especial notice. In the first place the objective was figured and corrected solely for visual purposes, and was therefore unsuited for photographic work, and in order to provide the necessary correction an auxiliary corrective lens was made to be mounted in front of the original lens. This corrective lens is of crown glass, thirty-three inches in diameter, and may be seen, in the illustration on the floor, on its carriage which has been provided for handling it. When this lens is placed in front of the regular objective, it not only makes all the corrections necessary for photographic work, but also shortens the focal length of the entire combination ten feet, thus making the position of the plateholder come some distance within the eyepiece. This permits the entire apparatus about the eyepiece to remain undisturbed when the telescope is used for photography, the holder and its attachments being introduced into the tube through an opening in the side.

Within the tube at this point is a carriage composed of two rings of about the inside diameter of the tube, these rings being connected together by four rods. On these rods the sliding portion of the carriage is fitted, and by means of screws the frame may be moved and adjusted in any desired position. As the rays of light from celestial objects are practically parallel, the camera is of fixed focus, and when the proper point is once determined, there is no use for any focussing screen, and the screw motion which acts on the carriage is provided with a pointer which indicates the exact focus. This pointer traverses past an index which is graduated for various degrees of temperature, for the expansion and contraction of the great tube would otherwise destroy the sharpness of the image.

The plateholder, twenty-three inches square, carries a plate 20×20, and slides into grooves in the carriage, where it is held by a spring. The holder is provided with shutters which are operated from without the tube, so that exposures may be made in that manner.

When an enlarged image is desired, the holder is not slid into the carriage, but in its place is put an enlarging lens of two inches aperture and twelve inches focus. This magnifies the image formed by the large objective, and projects it toward the eyepiece, which is then removed, and a small camera substituted to receive the enlarged image. This enlarging lens is fitted with a time and instantaneous shutter, operated from without the tube, so that enlarged photographs of the image formed at the focus of the telescope may be made direct, without being reproduced as in ordinary methods of enlarging.

Although the telescope as a camera has been in use such a short time, some very satisfactory work has been done, and the great light-gathering power of the thirty-six-inch objective will doubtless reveal detail in the photographic work that a smaller instrument would be unable to secure.

Great credit is due to Messrs. Warner & Swasey, of Cleveland, Ohio, for the skill which they have displayed in the designs for the mounting of the telescope, and for the care with which the work has been executed; and the success of the great camera is due quite as much to the designer of the mechanism as to the maker of the lens.

HENRY HARRISON SUTLEE.

DUTCH RIVER SCENERY FOR THE CAMERA.

IN TWO PARTS.—PART II.

Of the curious country, Holland, with which we have now to deal, one of the best brief descriptions I have seen was given in an old guide-book, which, after describing how nearly the whole country consists of land most industriously recovered from the sea, sets forth that the sea is higher than the land, sometimes to the extent of twenty-four or thirty feet; in no other country do the keels of the ships float above the chimneys of the houses, and nowhere else does the croaking frog look down upon the swallows on the house-tops. Cows' tails, says our author, in Holland grow upwards, instead of downwards, for, to promote cleanliness, each tail is tied up to a ring in the roof of the stable. Beckford, the author of *Fatrick*, writes that every flower which wealth can purchase blossoms on one side, and every stench a canal can exhale poisons the air on the other. The people live like frogs; "very slight authority would persuade me there was a period when Holland was all water, and the ancestors of the present inhabitants fish. A certain oysteriness of eye and dabbiness of complexion are almost proof sufficient of this aquatic descent; and pray tell me for what purpose are such galligaskins as the Dutch burthen themselves with contrived but to tuck up a bouncing tail, and thus cloak the deformity of a dolphin-like termination? In Holland the stork is revered as if it were a sacred ibis; cart wheels are sometimes placed for it upon the roofs of the houses, that it may build its nest thereon rather than block up the chimney.

One essential for making the long journey through Holland on board a Rhine steamship of any value for a trip with the camera is fine weather; nothing can be more dreary for paddling through a flat country than unbroken rainy weather. Another somewhat important requisite is that there shall be plenty of masses of cloud about, and that the plates used, combined with skill of the operator, shall render those clouds visible in the negative. Orthochromatic plates are said to be somewhat better than others in this respect, and the system of developing used by Mr. Payne Jennings, as described in Mr. Cadell's paper read at a meeting of the Camera Club, is successful in the rendering of the clouds in the field of view at the time of the exposure. With a flat river bank on each side, half of each plate exposed will be a perfect blank, so far as pictorial interest is concerned, unless the photographer secures picturesque masses of clouds, or goes to the trouble of printing them in afterwards. It is to be hoped that the time is at hand when the photographic world will not tolerate lantern slides representing landscapes without natural clouds, but will smother all such by universal consent after they have intruded their visages upon the screen. A day of rapid changes of sunshine and cloud, such as may be expected sometimes in April, is the day for the lower reaches of the Rhine. Should the weather not be suitable for photographic work of the kind described when the tourist arrives at Rotterdam, he had better stay there or thereabouts for a few days until a suitable morning arrives for giving him good cloud backgrounds.

What will he have in his foregrounds? Barges and ships, Dutch and German chiefly, of every size and description, some of them with wooden houses and small farmyard on deck, with the family linen drying on lines, the lady of the house doing the steering or other hard work, and a fat Dutchman, her lord and master, asleep over a pipe. Fancy a picture like this, with the rippling Rhine in the foreground, the cloud back ground, and the flat country stretching away into infinite distance. Some of the gigantic barges have what appear to be nine masts in sets of threes; there is the central mast and two others which spring on either side of it from the same part of the deck, but incline outwards as they rise, like the two arms of the letter V. These two additional masts are not really masts, but cranes; the long arms can be let down in any direction, and by suitable adjuncts pick up unconsidered trifles, such as small haystacks, and deposit them on deck.

Then there are the Dutch towns and villages which here and there adorn the banks of the river, with the houses internally and externally scrupulously clean: as seen from the river they might be set scenes from a

theatre, rather than real "practicable" houses used by real men and women. I saw one spotless house set as in a gilt frame; a band of gilt tracery about two feet wide, extended up both sides and along the top and bottom of the front. In the good old-fashioned Dutch towns and villages eternal rubbing and scouring are going on, with no litter in the streets, and everything as clean as a new pin. It is said that a pedestrian is liable to be deluged by a shower of water, and on looking up he sees the housewife at an upper window, where she has been surveying the front of the house above the window, and seeing, or fancying she sees, a speck of dirt on a brick, discharges a pail of water at it, of which the incautious ambulator below accidentally receives most of the benefit.

About the most interesting old-fashioned Dutch town on the Rhine visited by me was Nymwegen, where the boat arrived after dark and was moored for the night against a long and spacious quay, with the electric lights blazing from the tops of tall poles lighting up the nearest row of houses in the distance facing the quay; these houses, in all their brilliancy and cleanliness, looked like ideal dwellings constructed to adorn a theatrical scene. The Cathedral, lined nearly all over inside with clean, white, glazed tiles, was unlike any ecclesiastical edifice I had previously seen. One might almost venture to sit down anywhere in the streets without danger of soiling the garments, and ornamental articles in shops devoted thereto were specially bright and sparkling. The town looked like a place in which the intrusion of a spider would so excite the inhabitants that they would all turn out to give chase to the venturesome insect. In 1799, the Rhine rose here seven feet in one hour and nearly overran the province, owing to a vigorous thaw in the far away Swiss mountains.

Off most of the smaller towns or villages the steamer pulls up in the middle of the river, and passengers are taken on or off by means of a small boat. Here, then, are exactly the conditions the photographer wants; the steamer at rest off a picturesque Dutch village, and the vibrations of the engines stopped.

Should he be interested in large railway bridges he has every variety of them, some of them on small local lines, others on lines of international importance, such as some of those between Berlin and Belgium, or Western Holland. When he passes the Dutch frontier, and reaches Dusseldorf, he will find a bridge of boats, its elements composed of pairs of barges, with a section of a plank cart road across the tops of them. Some of these sections are furnished with steam engines, enabling them to quit their normal position in the line of barges, and to leave a gap through which the river craft can pass. Near one end of the bridge is a square, with an equestrian statue of John William, the Elector; this statue is said to descend from its pedestal and trot round the town on Walpurgis night; it is also said by the wise to be stuffed with treasure. Nearly under its shadow, and within hearing of the murmur of the mystic Rhine, Mr. Hubert was born, the romantic legendary surroundings of his youth doubtless have much to do with those flashings of genius with which he ever and anon irradiates photographic literature.

At Dusseldorf the tourist finds evidence of Germany being armed to the teeth, and scarcely anything but soldiers or officials of some kind, with gold lace about their hats, in all directions. I am told that the whole country is like one huge fortification under iron rule. A German launched out at me at one of the *cafés* there, in relation to England, that people who did not own the land on which their houses were built, but had the results of their industry taken from them by occasional rises in rent, were not a free people but slaves. This was not a polite remark to a foreigner, whatever truth there may be in it, and would not have been made by a Frenchman. I mildly asked whether Germany were not taxed to death, and young men forced into the army to the neglect of more useful pursuits. He admitted that taxation was heavy, but, he said, when a German has paid all his dues and performed all his duties to the State, all he gets by his industry is his own; no man can take it from him. He added that a few years' service in the army taught a youth the benefits of discipline and order, and made a better man of him. Another German subsequently denied this to me, and said that the service in the army had a thoroughly demoralising effect on the individual.

In Dusseldorf, as in many other continental towns, there is an English colony, said to number about a hundred all told. The residents in these Continental colonies are mostly persons of fixed and somewhat limited incomes, who live abroad because it is less expensive than living at home; also because education of children is much better and cheaper, and in some places the climate is better. I remember, with much pleasure, the kindness of reception in Dusseldorf given me by Dr. Liesegang, Mr. H. Schnus, Messrs. Otto Brothers, and some new and old acquaintances among the English residents.

A statement in my last needs correction, to the effect that the Rhine steamboats of the Dutch Company start from the same side of the river at Rotterdam as that at which the Harwich boats arrive. They start from the opposite side, and I was thinking of the head offices of the directors at the time of writing.

W. H. HARRISON.

BOLTON PHOTOGRAPHIC SOCIETY'S EXHIBITION.

THIS Exhibition, judging from the report in a local paper, seems to have been a good one. It remained open for only a brief period, and closed last Saturday. Medals were awarded as follows, although all the exhibits were not entered as competing:—

Competition No. 1 (for members only).—For the best six photographs taken since last exhibition: First prize, a silver medal with gold centre, John Johnston, M.D.; second prize, a silver medal, Walter Staton.

Competition No. 2 (for members only).—For the best six photographs: First prize, a silver medal with gold centre, Walter Staton; second prize, a silver medal, John Lomax.

Competition No. 3 (for members only).—Prize for the best and most artistic photograph entirely the work of the competing amateur, preference given to print from untouched negative, won by J. Johnston, M.D.

Competition No. 4 (for members only).—For the best series of six lantern transparencies, size, 3½ square: First prize, a silver medal with gold centre, Walter Knowles; second prize, a silver medal, James Leach. William Laithwaite was highly commended.

Competition No. 5 (for members only).—A gold medal given by Mr. John Taylor for the best six prints taken by members who have not practised photography more than three years, won by A. L. Entwistle.

Competition No. 6 (for professionals).—A silver medal with gold centre for the best series of six portraits, won by B. Wyles & Co., Southport.

A silver medal for the best landscape or marine view (also for professionals): W. A. Skill, Lincoln.

In this professional competition, J. P. Gibson, of Hexham, was highly commended.

The judges were Mr. A. W. Beer, Mr. W. A. Watts, and Mr. R. Crowe, all of Liverpool.

THE LATE EXPLOSION AT THE EAST WALL, DUBLIN.

THE INQUEST ON MR. BEWLEY.

THE City Coroner, Dr. N. C. Whyte (the 6th instant), resumed the adjourned inquest on the body of Mr. Thomas Arthur Bewley, who was killed on the 28th ultimo by an explosion of a gas cylinder.

Mr. Meldon, Q.C. (instructed by Mr. T. Overend) represented the next-of-kin.

Mr. Louis Meldon, solicitor, appeared for the Brin's Oxygen Board of London. The Coroner said that on the last day he was obliged to adjourn the inquest in order to communicate with her Majesty's Inspector of Explosives. Since then, aided by Mr. Semple and Sir Howard Grubb, he had collected a mass of information upon the subject as to how the explosion occurred, and whether it was likely to occur with a sufficient amount of caution. He wished to thank those who had come from a distance to help to elucidate the matter.

Mr. Meldon said that, appearing for the next-of-kin and also for the surviving partner, he would, if permitted, put before the jury the evidence which would demonstrate fully the nature of the cause of the explosion. Mr. Bewley carried on a large shipbuilding business, and, in addition, he manufactured certain gases. When it was required to make a powerful light, ordinary coal gas or hydrogen was used in conjunction with oxygen, the oxygen to make the flame much more powerful. In using these two gases when they came out of a nozzle there was no danger. Mr. Bewley supplied these gases to places of public entertainment. They were kept in cylinders—hydrogen in bottles painted red, and oxygen in bottles painted black. This rule was invariable. On the 27th December, Mr. Chancellor sent for a bottle of oxygen, and Mr. Bewley told him that he had not an empty black bottle then, but he supplied the oxygen in a red bottle, which should be used for hydrogen. He sent it to Mr. Chancellor, and it was not used then, but was returned on January 15. Afterwards Mr. Lawrence sent for two bottles, one of hydrogen and another of oxygen. Mr. Bewley forgot, and put in a small quantity of oxygen, thinking it was oxygen in the bottle, and sent it in as a bottle of hydrogen. This was discovered by Mr. Lawrence's assistant, for by putting a light to it there was a kind of explosion. He knew what was the matter, and put it aside and labelled the bottle "mixed gases." Mr. Lawrence wrote to the deceased saying that a mistake had occurred and that an accident might happen. Two days after the bottle was sent back to Mr. Bewley, and it was placed in the "drawing room," and remained on the table until the explosion occurred. Before that he told his foreman, named Ruthven, that the quantity of hydrogen was so small that there was no danger, and that he would himself use it, and on Monday, the 28th instant, he experimented with small quantities. Afterwards the explosion occurred.

After some further remarks from Mr. Meldon as to how the accident occurred, The Coroner said the important matter was, so far as he saw, whether the explosion was caused by friction. That point closely concerned the public, for those gases were used at theatres and public places of amusement, and while they did not want to cause anything like a panic amongst the public, it was their duty to inquire if any danger existed, or if such a result would be likely to occur again.

Sir Charles Cameron said he attended as Local Inspector of Gases. The Coroner announced that he had a communication from Major Kundel, one of the chief inspectors at the Home Office, with reference to the inquiry, and he said that the case did not come under the Act. When the Explosives Act was passed the compression of gases was not contemplated.

Mr. John Bewley examined, deposed that the deceased, Thomas Arthur Bewley, was his brother. Witness was in an office adjacent to where the explosion took place about 4.25 p.m. on the 28th January. He heard a slight report and crash of glass, and he immediately rushed out, and saw his brother lying on his back he was dead. There was nobody in the room with the

deceased. He used this room for drawing, but had no mechanical appliances in it.

By Mr. Meldon: The deceased told him that he had put oxygen into a bottle ordinarily used for hydrogen and sent it to Mr. Chancellor. Witness said it was wrong to do so without painting the bottle of a colour that would indicate that it contained oxygen.

By the Coroner: For some months past they had not manufactured any oxygen, but had imported it. They made the hydrogen.

The Coroner invited several scientific gentlemen to put questions to the witness, and in reply to questions he said that there was a gas jet in the room where the accident occurred.

By Mr. Meldon: Steel cylinders were used for a much greater pressure than iron ones.

In reply to another inquirer, the witness said they were accustomed to put seven hundred and fifty pounds or eight hundred pounds of pressure in the cylinder, while they might safely put two thousand or even two thousand five hundred in them without in any way injuring the material. The particular bottle which burst was carefully examined, and no flaw discovered in it.

The Coroner said that they had now got over the question of pressure being the cause of the explosion. *Prima facie* it would appear that fire caused the explosion, and he would like to hear something about the friction or light.

Mr. F. Scarr deposed that he was cashier and book-keeper to Mr. Bewley, and as an additional duty he had charge of those bottles coming in and going out. He dealt with them only as merchandise, and had nothing to do with the filling of them. About twenty of those bottles went out every week. There were two regular assistants, one of whom was a scientific man. He received the bottle back from Mr. Lawrence referred to by the last witness, on the 10th January. A proper oxygen bottle was afterwards supplied to Mr. Lawrence. A bottle of hydrogen was also supplied. The oxygen bottle which was received from Mr. Lawrence was left in the drawing room.

By the Coroner: Two or three long bottles of about one hundred feet in each went to the Leinster Hall every day during the Christmas season.

John F. Ruthven, a labourer in the employment of Messrs. Bewley, deposed that up to a short time ago he assisted in filling bottles with gas; on the Saturday before the accident he saw a red bottle in what was known as the drawing room at the North Wall. He told Mr. Bewley to allow the gas to escape as it was mixed. Mr. Bewley explained that before Christmas-time, having no oxygen bottles, he took a hydrogen bottle and filled it with oxygen for Mr. Lawrence, believing that it was to be used that night. Forgetting there was oxygen in it he put in hydrogen to bring it up to the required pressure. The bottle came back marked "mixed," but he said there was so little hydrogen in it that it was not dangerous, and used experiments to prove to witness that it was not dangerous. He explained that, as in the case of this bottle, when there was a small quantity of one gas mixed with a great quantity of another kind of gas there was no danger. He transferred some of the gas to another bottle and equalised the pressure, which in each case was four hundred pounds. He intended to use one of the bottles at an entertainment that night. When filling one bottle from the other there was some difficulty in making the connexion with the tube. When witness left Mr. Bewley in his room about two o'clock there was a branch of gas lighted, but the light was very low. Mr. Bewley was very careful in handling the bottles.

Archibald M'Williams, a labourer in the employment of Messrs. Bewley, gave evidence also.

Mr. Lang deposed that he was giving a magic lantern entertainment at Naas for Mr. Lawrence. He brought down the bottle which subsequently exploded for the purpose of the limelight. He attached it to the hydrogen pipe and applied a light. An explosion took place, blowing off a pipe of the lantern and blowing out a candle. He tried to light it again, and there was another explosion. He got a new cylinder and went on with the entertainment.

Professor Barret, who gave evidence as an expert, stated that having heard all the facts as deposed to, he had no doubt that the true cause of the explosion was the mixture of the oxygen and hydrogen gases. He did not think that friction would cause the explosion, and he could explain it in no way except that the gas jet in the room was possibly lighted. He explained that there was no serious explosion when Mr. Lang lighted the magic lantern jet by the fact that the cold mass of metal stopped the flame from entering the cylinder. When pure oxygen, hydrogen, or coal gas were kept in separate bottles, and used with a jet such as had been used by Mr. Lang in this case there was no danger. He suggested, however, as the compressed gases are coming into general use at the present day, it is most desirable that the Government should recognise the fact and appoint an official, whose duty should be—(1) from time to time to inspect the arrangements for compressing the gases; (2) certify that the cylinders are able to bear at least twice the pressure to which they were charged; (3) see that some distinctive, uniform, and indelible mark is attached to the hydrogen or to the oxygen cylinder; and (4) pass a short Act rendering it penal (for commercial purposes) to compress oxygen in a hydrogen cylinder or vice versa.

Professor Hartley stated that he inspected the scene of the occurrence. He agreed generally with what Professor Barret had said. He came to the conclusion that this accident was the result of the detonation of the gases within the cylinder. He believed the rupture to be caused by a chemical combination of the gases. The gases within the bottle might explode by other causes than the application of external flame; a little oil or rust might have caused the

rupture. Chemical combinations could by various means be brought to an explosion.

By the Coroner: He did not consider that there was any danger in storing hydrogen, but it should be understood that it was hydrogen, and not mixed with oxygen. To preserve such a combination was unwise. He did not fear any danger from preserving oxygen alone under pressure. There should, in his opinion, be no chance of allowing oxygen to be put into hydrogen bottles, or vice versa. As a precaution against such an occurrence, he would suggest that the screws for the bottles should be of a different size. He did not see that the public had any cause for alarm when ordinary precaution, such as suggested, was exercised.

Mr. J. V. Robinson was examined. He was present at the charging of the cylinder that burst. The pressure was eight hundred and eighty pounds, and he believed that the pressure caused the explosion. He believed that the iron was not in a good condition. He had a thorough knowledge of the bottle as it was made from a bottle the model of which he introduced.

Mr. Mellon pointed out that it was tested up to a much higher point.

Dr. Myles deposed that the death of Mr. Bewley was due to injury to the skull and spinal cord. Death was instantaneous. It was not possible, as suggested, that the gentleman's watch could have been blown into his body.

Sir Howard Grubb was examined. He deposed to having examined the place where the accident occurred. He came to the conclusion at the time, and had not changed his opinion since, that the accident occurred by the ignition of mixed gases. In the face of the facts before them, as to the bottle of mixed gases at low pressure, and Mr. Bewley having announced his intention of experimenting, there being a light in the room, he thought they might go no further.

The Coroner said there was no evidence that there was a light in the room at the time of the explosion.

Mr. Goggle, of London, deposed that he was conversant with the use of these cylinders containing gases. In the establishment he represented they were used as in Mr. Bewley's. He believed that the cylinder was capable of sustaining four hundred pounds pressure.

The Coroner, in his remarks to the jury, said that no blame could be attached to any one. There was a mistake committed in mixing the gases, and as suggested by one of the scientific witnesses, he thought that a mixture of them should be made penal.

The Jury returned the following verdict:—"We find that Thomas Arthur Bewley was killed instantaneously on the 28th January, 1889, at the yard of Messrs. Bewley, Webb & Co., East Wall, by the accidental explosion of a gas cylinder, used for the purpose of limelight, and we are of opinion that the accident was caused by the mixing of the two gases, oxygen and hydrogen—how exploded we have not sufficient evidence to show; and we are further of opinion that the authorities should take steps to protect the public against similar accidents by affixing a Government stamp on all cylinders used for such purpose."—*Irish Times*.

Our Editorial Table.

GAEDICKE'S MONOCHROMATIC DARK-ROOM LAMP.

A MONOCHROMATIC light is proverbially a safe one in the dark room. Up to the present time no simple and efficient lamp has, so far as we are aware, been introduced for giving such a light and for such a purpose.

Herr Gaedicke has devised one, or more correctly two lamps, one burning with gas, the other burning with alcohol. Both are respectively shown by the adjoining cuts. The one which we have examined, however,

is for gas, and as such we will attempt its description. A Bunsen burner of small dimensions is surmounted, at a little distance from its orifice, by a holder containing a ring of asbestos. This is adjustable in every direction.

To prepare the lamp for burning, this asbestos is moistened with water and a little finely crushed common salt sprinkled upon it. It is now ready for lighting. The flame is protected by a brownish-coloured

chimney, and when the lamp is ignited it emits a considerable volume of light. Provision is also made for interposing a plate of coloured glass between the flame and the object to which it is to be directed. The asbestos requires to be dipped in water and sprinkled with the salt once in every ten hours it is burning. It is, indeed, an effective little dark-room appliance, and we can readily understand how the German Photographische Association awarded a diploma for it last year.

Marion & Co., 22 and 23, Soho-square, London, are the sole agents in this country.

TRADE CATALOGUES.

Mr. H. H. SHARLAND, Thavies-inn, E.C., sends us his wholesale and export list of all kinds of optical and mathematical instruments. Its 146 pages, quarto, are literally crowded with engravings of the various objects manufactured or supplied by this firm. Telescopes, microscopes, binoculars, levels, barometers, polarising prisms and appliances, and everything pertaining to the optical trade are here to be found. It is, however, a private wholesale list for the trade only.

The catalogue of Nadar, Paris, which pertains exclusively to photographic appliances, is very comprehensive. Being intended for French readers, it is printed in that language. It partakes very much of the nature of our own catalogues published in this country.

RECENT PATENTS.

APPLICATIONS FOR PATENTS.

No. 1925.—"Improvements in or relating to Tailboards of Photographic Cameras and Means of Attaching Body of Camera to same." H. HERBERT.—*Dated February 4, 1889.*

No. 2181.—"Improvements in Photographic Camera Pinions." J. C. BARNES.—*Dated February 7, 1889.*

PATENTS COMPLETED.

NEW OR IMPROVED ARRANGEMENTS OF DRAWERS, OR ARTICLES OF FURNITURE, FOR EXHIBITING AND HOLDING PHOTOGRAPHS, CARDS, PICTURES, AND THE LIKE.

No. 2975. HARRY HEATE, 8, Kingamead road, Oxtou, in the county of Chester.—*February 25, 1889.*

IN place of having a simple album to contain photographs, &c., I form a revolving stand with two, three, or more sides, or even a cylinder.

Each side of the stand, or small arc of the cylinder, is formed of a door or doors having a panel or panels containing the photographs or other articles to be exhibited, both inside and out. These doors are formed in two or three layers, on one of which the photographs or other articles are attached, while the outer one (or ones) form a framework round the photographs, so that they can be seen, as it were, encoined in a frame.

The two or three layers can be fastened together by ornamental screws or otherwise, or in the case of innermost doors they can be simply fastened by a spring catch or otherwise.

It will be obvious that there can be a large number of these doors one behind the other, until nearly the centre of the stand is reached.

The case preferably revolves on a pivot on its stand, and this stand can be either a flat board for standing on the table, or tripod, or even a small chest of drawers, or box for containing articles, or it can be arranged as an open cupboard or whatnot in which music and other things can be placed, the photograph case swivelling on a pivot on the top.

The doors of the photograph case can be of ornamental wood, plush-lined, or any other fancy material that may suggest itself to the designer.

In some cases electric or other lights can be fixed behind the photographs so that transparencies can be used, the article of furniture then becomes to some extent a lamp.

The way I prefer to arrange the doors is as follows:—If the article is a pyramidal shape the lower half of the door turns on hinges on its lower edge and falls horizontally, being prevented from falling further by tapes or chains. The upper half can be formed in one or two doors opening sideways on hinges.

IMPROVEMENT IN PLATE-LIFTING APPARATUS FOR WORKING METAL SHEATHS UNDER A BAG IN CONNECTION WITH DETECTIVE AND OTHER CAMERAS.

No. 4145. SAMUEL WHITE BUNCH, 180, Strand, London.—*March 17, 1888.*

THIS invention has special reference to my patent, No. 6613, dated May 5, 1887, in which photographic plates were transferred from front to rear after being impressed with a latent image.

But I now reverse this order and lift the plate from the rear to the front, the appliance for doing so being affixed to the back cover of the reservoir, instead of being in the body of the camera as formerly. This secures, among other advantages, that of being enabled to apply any of the rapid class of shutters which are formed for working immediately in front of the sensitive plate.

The method by which I effect this is as follows:—A metallic or other lever is placed in the back of the reservoir, preferably sunk into it, and covered up by an inner lining of wood; one end projects outside of the reservoir, the other end is bent at a sharp angle, and is left sufficiently long for the last or rear plate of the series to rest upon. On depressing the outer or exposed end of the lever, the other end, which rests at the bottom in a recess and upon which the

posterior plate stands, is raised, and carries upwards with it that plate to a certain determinate height, the plate being prevented from falling downward again by means of a spring catch. On releasing the outer end of the lever it immediately resumes its former position by the agency of a spring. The plate, which is half raised up, and is reposing upon the spring catch, is now taken hold of by finger and thumb through the opaque suede leather or other bag, as described in my former patent, and is transferred to the recess in front of the reservoir, and upon being pushed down is in the focussing plane ready for being exposed; after which, by depressing the lever and repeating the process just described, another plate is transferred from the rear to the front, and so on in succession.

The reservoir with the various fittings may be made distinct and separate from the body of the camera, and fitted with the usual slide in front. This enables me to provide any number of such reservoirs to any one camera, so that a photographer may go on a tour provided with such a number of these, all stored with sensitive plates, as to be practically illimitable.

(Here follow references to drawings.)

What I claim is—1. The mode of transferring the plate from back to front by the lever, as herein set forth. 2. The spring for ensuring the retention of the plate after being raised. 3. The return of the raising lever to its normal position by means of a spring. 4. The separate reservoirs fitted with the appliances described as distinct from the camera, and capable of being attached to or inserted in the camera the same as an ordinary dark slide.

AN IMPROVED FORM OF CAMERA FOR OBTAINING PHOTOGRAPHS OF MOVING AND OTHER OBJECTS.

No. 4248. FRANCIS NOWLAN, 17 Soho-square, London, Middlesex.—
March 20, 1888.

A PHOTOGRAPHIC camera, the plate carrier of which is in the form of a drum, capable of carrying a number of plates, which plates are held in position inside the said drum by a series of flat spokes and made to rotate on an axis. The face of the plate when in position being at right angles to the focal axis of the lens.

By turning a small knob on the outside attached to the axis the plates can be brought in rotation to face the lens, their true position being automatically registered by a spring, such as in use on rotating lens stops.

A shutter is arranged inside the drum and actuated from the outside which, when desired, covers the opening in the periphery of the drum in connexion with the lens. The sides of the drum complete the exclusion of light; one side of said drum may be attached to the shutter and revolve with it, the other side being removable, to enable the plates after exposure to be taken out and fresh ones put in. The removable side has an opening in its centre to allow a continuation of the axis forming the knob to project through, by turning which knob the plates inside are brought into position after every exposure, light being completely excluded by a slight shoulder surrounding opening for knob.

On the outside of the periphery of the drum is an opening corresponding in dimensions with photographic plates carried inside. To this opening is fitted a telescopic neck to carry the lens. The neck may be either round or square, square by preference. Through said neck the rays of light passing through the lens reach the sensitive photographic plate inside the drum.

To insure that the object to be photographed shall be accurately projected on the sensitive plate a finder or sight of a novel type is attached to the camera as near lens as possible, and may be fastened either to the neck holding the lens or to the inside of the knapsack case which encloses the whole apparatus. The said finder consists of a small mirror, either flat or convex, the convex by preference as it may be selected of such a curvature as will give reflections corresponding in size with image projected by the lens on the sensitive plate, the said mirror thrown back to an angle of 45° is placed immediately behind two cross wires and reflecting their intersecting point. Any object in front of the camera visible in mirror in conjunction with intersecting wires and viewed from the proper angle in relation to reflecting surface of mirror will be on the plate in camera should a photograph be taken, the intersecting point of wires representing the exact centre of the sensitive plate.

To enable the operator to view mirror from the proper angle an eyepiece or rim of wire is placed in such relation to the mirror that when the operator's position is correct he can see the reflection of cross wires central with the solid eyepiece. The operator need not place his eye in close position, but may be removed from finder as far as his eyesight will allow him. No screening of the surrounding light is necessary, it being simply a reflection in a mirror having the correct angles regulated by a combination of a solid eyepiece with reflection of cross wires.

This arrangement allows the operator to obtain photographs of objects on either side of him without turning his head or body in the direction of the object to be photographed, and to follow such objects about, keeping them constantly in position till he finds the pose or action suitable.

Any existing instantaneous shutter may be used for exposing the plates in the ordinary manner.

The knapsack case enclosing all having openings to face the lens and view meter. A small spirit level will also be necessary. When focussing is necessary for change of lens or any special purpose the drum containing sensitive plates can be drawn out. The telescopic neck being in two parts, one sliding inside the other, the forward portion carrying the lens being fixed to front part of knapsack case, the drum and remaining portion of neck drawing away along regulating grooves and out through opening at back of knapsack. When the drum is removed for focussing a ground glass is suspended inside knapsack on the same plane which the sensitive plate will occupy when the drum is returned to position. The necessary focus obtained, the drum is replaced. A block secured in position while focussing registers the position of the drum in regulating grooves and secures plates in focus.

The claims are:—1. In photographic cameras a multiple plate carrier or drum carried within a second or surrounding drum and adapted to hold a given number of plates and to present them in order to the lens opening substantially as described. 2. In photographic cameras a view meter or finder, consisting

essentially of a mirror and cross wires or lines adapted to be reflected thereon, and secondary wires or lines acting as an eyepiece or point of view, the parts being so arranged that the portion of an object reflected on said mirror where the secondary wire appears to coincide with the reflection of the front cross wires will be also in line for transmission to the centre of the plate substantially as set forth. 3. The general arrangement and construction of parts forming the improved multiple plate camera substantially as and for the purposes described.

CERTAIN IMPROVEMENTS IN PHOTOGRAPHIC CAMERAS.

No. 18,026. WILLIAM CHANNING GIBBS, 303, California-street, and GEORGE WILLIAM DORNIN, 215, Sansome-street, San Francisco, California, U.S.A.,
December 11, 1888.

Our invention relates to the class of photographic cameras; and our invention consists in the novel construction and arrangement of the inclosing case, box, or frame, whereby its back and front plates, when dropped to expose the operative parts of the camera, are made to serve as the supporting bed, and the focussing platform, respectively; in the novel adjusting or focussing carriage; in the adjustable support for the finder; and in details of construction and arrangement, all of which we shall hereinafter fully describe.

The main object of our invention is to provide a photographic camera which needs no separate box or case, having within itself parts which, ordinary essential to its operation when in use, yet have the further function of completing a perfect case or box, so that the camera is self-contained.

Other objects are to provide improved constructions for focussing the lens, and supporting the finder. After referring to certain drawings, the patentees state their claims as follows:—

1. In a photographic camera, a plate which, when closed, forms one end of the camera-frame, and so hinged thereto as to adapt it to be dropped down to expose the camera end, and turned under to form a bed or support for the camera-frame, substantially as described. 2. A photographic camera having a body-frame with a hinged back plate adapted to be dropped down to expose the camera back, and turned under to form a bed or support for the body-frame, substantially as described. 3. A photographic camera, having a body-frame with a hinged back plate adapted to be dropped down to expose the camera back, and turned under to form a support for the body-frame, and a proper fastening for holding the plate steady under the body-frame, and a fastening under said plate for the tripod, substantially as described. 4. In a photographic camera, an open-ended body-frame, a plate forming one of its ends and hinged thereto, adapting it to be turned down to expose the camera-end and form a focussing platform for its adjustment, and a second plate forming the other end of the body-frame and hinged thereto, adapting it to be dropped down to expose that end of the camera, and turned under the body-frame to form a bed or support therefore and for the other end-plate, substantially as described. 5. In a photographic camera, an open-ended body-frame, a plate forming one of its ends and hinged thereto, adapting it to be turned down to expose the camera end and forming a focussing platform for its adjustment, a second plate forming the other end of the body-frame and hinged thereto, adapting it to be dropped down to expose that end of the camera, and turned under the body-frame to form a bed or support therefore, and for the other end-plate, an automatic catch-connexion between the two plates to hold them firmly together, and a fastening for holding the second plate solid under the body-frame, substantially as described. 6. In a photographic camera, the adjustable support for the finder, consisting of the plate secured to the finder, and having opposing shoulders by which its movement is limited, and the arm pivoted to the front board of the camera and to the finder-plate, and having a pin for coming in contact with the shoulders of said finder-plate, substantially as described. 7. In a photographic camera the focussing or adjusting mechanism, consisting of the carriage frame on which the camera front is mounted and adapted to slide, the fixed tracks on which the carriage frame moves, the notches in the tracks, and latches on the carriage frame for holding said frame to the position to which it is adjusted, and the pinion shaft on the camera front, and racks on the carriage frame for adjusting the camera front on said carriage frame, substantially as described.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Date of Meeting.	Name of Society.	Place of Meeting.
February 19.....	North London	Myddelton Hall, Upper-st., Islington
" 19.....	Glasgow & West of Scotland Am.	180, West Regent-street, Glasgow.
" 19.....	Bolton Club	The Studio, Chancery-lane, Bolton.
" 20.....	Bristol and W. of Eng. Amateur	Queen's Hotel, Clifton.
" 20.....	Bury	
" 20.....	Burley and District	Meehan's Institution.
" 20.....	Hyde	
" 20.....	Manchester Camera Club	Victoria Hotel.
" 20.....	Edinburgh Photo. Club.....	5, St. Andrew-square.
" 20.....	Photographic Club	Anderson's Hotel, Fleet-street, E.C.
" 21.....	London and Provincial	Masons Hall Tavern, Basinghall-st.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

Last Tuesday night, at the annual general meeting of the above Society, held at 5A, Pall Mall East, London, Mr. James Glaisher, F.R.S., President, occupied the chair.

Mr. W. S. BIRD then read the report of the Council, which set forth that during 1888 the problem of modifying the sensitive film in the direction of securing orthochromatic results from coloured objects has been diligently studied, and some comprehension of the chemical reactions by which certain

dyes combining with the silver haloids of the sensitive film tend to restrain the actinism of the violet end of the spectrum, and to increase it in the yellow and red rays, is being gradually acquired. The effect of the interposition of coloured screens has been considered, and the use of coloured light in connexion with this problem has been essayed, and has helped to throw upon it some intellectual light. That the practical outcome of these researches has enabled photography to translate the colours of nature and of art into monochromatic effect, much more in accordance with the visual impression of such colours than formerly, cannot be doubted, but much has yet to be done to attain perfection. Two members of the Society, Captain Abney and C. H. Bothamley, have done notable service in placing orthochromatic photography on a scientific basis. The optical conditions of the art-science have not been neglected by the Society during 1888; stereoscopic and binocular vision, depth and diffusion of focus, and optical lanterns, have received considerable attention at its meetings. The following is the analysis of the 1888 Exhibition:—There were one hundred and fifty-eight exhibitors, comprising one hundred and three members and fifty-five non-members. There were five foreign exhibitors (America one, France one, Germany two, Belgium one). The one hundred and fifty-eight exhibitors comprised seventy-five professionals and eighty-three amateurs. Five hundred and eighteen frames were hung, containing one thousand and ninety-eight separate photographs, consisting of three hundred and twenty-three portraits, one hundred and nineteen figure subjects, six hundred and eleven landscapes and architectural subjects. There were twenty-five marine views and twenty animal subjects; these, with photographs on the table (including one hundred and eighty-two transparencies), made up a total of one thousand three hundred and thirty photographs. These figures show a falling off in the number of professional exhibitors about one-third less than in 1887, and also a considerable reduction in non-member exhibitors; the total result showing a diminution of nearly one-fourth in the number of exhibitors as compared with the previous year. The apparatus exhibits were few, but they included some interesting examples of the ingenious application of mechanical skill to facilitate the growing capabilities of dry-plate work.

Mr. JOHN BRILLER moved, and Mr. WILLIAM ENGLAND seconded, the adoption of the report.

Mr. T. HANFELS remarked that there had been a falling off in the number of the exhibitors and of members. The report did not give the opinion of the Council as to the effect of the abolition of donations of medals for the best work on view at the exhibitions. He had expected some reference as to what the Council would do in this matter in the future.

The President replied that at that moment the Society had no Council, as decided by the new rules, and the old Council could not say what the new Council might do.

Mr. HANFELS added that it might nevertheless give the new Council the benefit of its experience.

Mr. WILLIAM BEDFORD thought that that general meeting of the members might express an opinion for the guidance of the new Council. He hoped that in future non-members would not have to pay for wall space at the exhibitions, which should be free and open. He welcomed the increasing number of photographic exhibitions on a commercial basis, but the Photographic Society should be in a position to hold itself superior to such considerations.

Mr. BIRD said that the main question was one for the members rather than for any Council to decide.

The President stated that several members of the Council, who had voted for the abolition of medals, had expressed to him their disappointment at the result. The report was then adopted unanimously.

Mr. BIRD, Hon. Treasurer, then read the Treasurer's Report, which stated that despite a falling off in 1888 of over 50% in the value of subscriptions, and a diminution of nearly 24% in the receipts by admission to the exhibition, the capital of the Society has increased by 138*l.* 12*s.* 6*d.*, by far and away the largest on record, the balance in favour of the Society being now 665*l.* 12*s.* 11*d.* The total expenditure of 1887 amounted to 786*l.* 11*s.* 6*d.*, and that of 1888 to 73*l.* 11*s.* 9*d.* less. Of this diminution the exhibition cost less by about 50*l.*, and the difference was saved on smaller items. 150*l.* will be added to the Society's investment in Consols. The account of receipts and disbursements given results not entirely satisfactory, in consequence of the diminution on account of entrance fees and subscriptions, and a smaller yield by admissions to the exhibition. The latter item is subject to fluctuations from various causes; but diminishing number of members, commencing in 1887 and continued in 1888, can only be regarded as a sign of weakness. The great development these two years of photographic societies and clubs, both in London and the provinces, has perhaps something to do with the fact, but if as it only teaches the lesson that the Parent Society must be true to its history and strive to keep the lead in all matters of photographic science and art.

Mr. H. M. SMITH asked if the Society could not affiliate provincial societies; many would be glad to join.

The President replied that he had been urging that plan for some little time. No doubt the question would come before the new Council.

Mr. T. SEBASTIAN DAVIS moved the adoption of the report, and thought that the suggestion of their Yorkshire member should be considered by the new Council. The Society was in a flourishing condition, with more than 900*l.* in hand, which would be 2*l.* per member if ever they had to divide.

Mr. W. K. DENKHAM seconded the adoption of the report.

Mr. J. W. SWAN, M.A., then read a paper on *Hydroquinone as a Developing Agent*. [We shall not spoil the completeness of Mr. Swan's paper by giving a synopsis of it, especially as it will appear next week with the author's annotations.]

At the suggestion of Mr. COWAN it was agreed that the negatives should be examined and considered at the next technical meeting of the Society.

Mr. A. MACKIN asked why the samples of hydroquinone exhibited differed so in tint and appearance.

Mr. SWAN replied that they were commercial samples, and he could not answer the question.

Mr. WELLINGTON would like to see prints from the negatives; he thought that some of the worse-looking ones might just last.

On the motion of Mr. FRANK GREENE the discussion was adjourned.

THE first annual dinner of this Society took place in the Café Royal, on Monday evening, which was also that of the monthly dinner of the Solar Club, with which it was amalgamated for the occasion. Although there was a fair attendance (seventy-eight gentlemen and six ladies), many old and leading members of the Society were "conspicuous by absence." Mr. Glaisher, F.R.S., as representing the Society, presided, the vice-chair being occupied by Mr. John Procter of the Solar Club. Following the example of some of the provincial societies, the menu card was illuminated by a portrait of the President.

After the loyal toasts came that of the "Photographic Society of Great Britain," proposed by the President.

Having alluded to the new rules that had been drawn up recently for their guidance, he said this may be considered the jubilee year of the photographic art, as fifty years had elapsed since Daguerre's time. Their own Society had been in existence for thirty-six years, and he was sorry to say they had been without a home all that time. It would be exceedingly desirable that they should have such a home, and he hoped that all photographers would unite and have one in common.

In proposing the toast of "Kindred Associations," the President said that this Society had all along held out its hands to them; whether those at home or abroad they had their very best wishes. He would like to see them all connected with this Association by way of affiliation or otherwise.

Messrs. G. DAVISON, FRANK GREENE, and L. WÄRNERKE, responded, the last speaking of the value that would accrue from the establishing of a photographic college.

Messrs. J. TRAILL TAYLOR and C. W. HASTINGS responded to the toast of "The Press."

In giving the toast, "Their President," Mr. J. R. DALLMEYER said that all felt and appreciated Mr. Glaisher's untiring energy and devotion to their interests, and considered him as the backbone to the Society, and hoped he would be spared to them many years.

Mr. GLAISHER made suitable acknowledgment of the toast.

The toast of "The Ladies" was given in a humorous manner by Mr. COWAN, jun., and responded to by Mr. W. S. BIRD.

There were the usual sprinkling of songs, recitations, &c.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, last week, at the ordinary weekly meeting of the above Association, held at the Masons' Hall Tavern, City, London, Mr. P. Everett presided.

Mr. C. H. COOKE wished to know how to make the best transparencies for enlargement by means of the camera; he found those on paper to be generally hard or else of a bad colour; he thought a slow bromide plate to give as good a result as obtainable by the carbon process.

Mr. W. E. DENKHAM said that as carbon tissue when wetted expanded in one direction more than in another, distortion was introduced; he thought that the best transparencies he had ever made were by printing out on chloro-chloride in gelatine.

Mr. A. HADDOX stated that if he wished to enlarge from a 10×8 or 10×12 negative the use of a condenser would be out of the question; what would then be the best method of procedure?

Mr. DENKHAM believed the placing of several gas jets behind two sheets of ground glass; the coarsest sheet of ground glass should be near the lights and the finest sheet near the picture.

Mr. J. TRAILL TAYLOR thought that the best plan. Three gas flames would be sufficient.

Mr. A. COWAN had found very even illumination to be given by lighting up the surface of a sheet of card; the waste of light thereby was not seriously expensive.

Mr. HERBERT STARNES remarked that a friend had asked him whether he could rig up a water condenser by means of a flat sheet of glass on one side and the glass cover of a clock face on the other side, cemented together at the edges and filled with distilled water.

Mr. TAYLOR replied that clock glasses were of a lunette form, and rarely segments of a sphere, and that the more salts the water contained the better, to shorten the focus.

Mr. DENKHAM said that salts of mercury in solution in the water would be good.

Mr. J. B. R. WELLINGTON had made as good enlargements from collodion-bromide as from carbon transparencies, and could work by gaslight.

Mr. W. BEDFORD said that with carbon almost perfect contact with the negative was obtained, and that in enlarging diffused light was necessary because of the defects in the glass.

Mr. DENKHAM asked why specially prepared collodion-bromide films on paper should not be used.

Mr. COWAN said that the collodion-bromide film was excessively tender and required care in manipulation.

Mr. WELLINGTON responded that a little practice overcame that difficulty.

Mr. COOKE had found collodion-bromide plates to harden with a day's keeping; they should always be prepared a day in advance, otherwise scratches are almost sure to be produced in working them.

Mr. HADDOX questioned whether warming the fresh plates would not give the same result.

Mr. COWAN thought that carbon tissue for the purpose should be prepared on plate glass covered with a film of collodion to obtain a true surface.

Mr. TAYLOR said that a better plan than using fluid condensers was to get a sheet of glass nicely bent and silver it, then use it as a reflector. Some years ago he made large burning mirrors by grinding the upper edge of an iron vessel like a saucer quite flat, rubbed Canada balsam over the rim, placed the glass over it and exhausted the air. Amongst other means to effect a vacuum, he put a little lighted paper in the saucerpan then quickly put a sheet of glass over all as a cover; as the heated air inside cooled a partial vacuum was produced, and at the end of the operation the glass was beautifully curved. The piece of glass had been previously silvered.

Mr. HADDON stated that that plan had once been suggested for the manufacture of astronomical mirrors; he did not know whether they would then be sufficiently true.

Mr. STANNIS remarked that when transparencies required "dodging" the collodio-chloride printing out process was good; it gave a fine range of tone, and the operator could see what he was doing. The plates could be prepared by means of a mixture of calcium chloride, collodion, and silver nitrate, and then dried at the fire. The presence of no organic salt is necessary. In dull light the nitrate of calcium formed in the film may have time enough to get clumped and stick to the negative; the process is one for fine weather.

Mr. DEBENHAM thought that chloride of strontium should be substituted for chloride of calcium in making the emulsion.

Mr. TAYLOR remarked that there was a theoretical, although perhaps not a practical, objection to the carbon film for enlarging; different parts of the picture varied in thickness, causing refraction at the edges of high lights.

Mr. HADDON added that, therefore, the film itself acted as a lens.

Mr. DEBENHAM said that when the light was powerful it was not a bad plan to put ground glass in front of the condenser.

Mr. F. A. BRIDGE said that sometimes ground glass was placed between the lenses of a condenser, and it was said that that plan would enable good work to be done with a bad condenser.

Mr. DEBENHAM remarked that in reproduction operations the faults of the original were reproduced and fresh ones added. Some faults, however, could be removed by enlarging; for instance, in those cases in which the negative was too intense or not intense enough.

Mr. BRIDGE had found that negatives for enlarging should be rather thin and full of detail, then the light should be modified to suit the negative. With a slow bromide paper it is more difficult to get a good result with a dense negative, and increasing the exposure will not get over the difficulty.

Mr. HADDON said that negatives for enlarging could hardly be too thin.

Mr. HADDON stated that more than twenty years ago direct enlarging was done upon common albumenised paper by means of Van Monckhoven's apparatus.

Mr. STANNIS questioned whether in the action of light upon photographic salts some inertia had not to be overcome and that a certain power of light was necessary to initiate action.

Mr. HADDON thought all developers to be imperfect, and that those imperfections had to be compensated by increased exposure.

Mr. DEBENHAM did not agree with those who said that as bright a picture could not be obtained with a smaller stop and longer exposure; a weak light acting for a long time would give the same result as a strong light acting for a short time, all other conditions being the same.

Mr. BRIDGE did not think so; he had not found it to be so in enlarging.

Mr. DEBENHAM also did not believe that there was any advantage in printing a weak negative in the shade instead of in direct sunlight. On the same sheet of paper and with a thin negative he had printed one image in sunlight in one and a half minutes; another image he had printed indoors, in deep shade, in one and a half days; and a third image in two and a half days; the results were so much alike that most people could not tell which was which. A strong light means also heat, and when the paper gets hot there is a tendency to yield weaker print.

Mr. COOK had a yellowed print which required copying. Would an orthochromatic plate be best for the purpose?

Mr. DEBENHAM replied that it would, and that a yellow screen should be used. The latter was apt to interfere with sharpness.

Mr. WELLINGTON had not found patent plate covered with a stained film to interfere with sharpness.

Mr. TAYLOR said that Mr. Beck, after his lecture before the Society of Arts, had suggested the use of a yellow glass cover to the lens cemented in optical contact therewith.

Mr. HADDON stated that a newspaper report now before them of the inquest on Mr. Bewley, at Dublin, did not seem to throw much light on the cause of the explosion itself. The bottles may have been of mild steel; they were tested up to two thousand pounds per square inch, and the pressure of the gases in them was from seven hundred and thirty to eight hundred pounds per square inch. One bottle had hydrogen in it, and they then compressed some oxygen into it, although the bottles were distinctly marked. Mr. Haddon, after giving a synopsis of the published report of the inquest, added that the velocity with which compressed gases come out of such iron bottles is so great that it prevents flame passing backwards into the bottles; this had been proved by experiment. Perhaps when turning the tap to diminish the rush there may have been a back flow, as with the ordinary Bunsen's burner when it is turned too low. If once flame found its way inside the cylinder the pressure of the gases there would not prevent an explosion; in ordinary gas engines, for example, the gases are always fired under pressure.

Mr. HADDON considered it to be almost an insult to scientific men to make, as a witness had done, the suggestion that it should be made penal to try experiments with the mixed gases.

The CHAIRMAN was of the same opinion; the bottles in the instance before them had both been tested and marked with distinctive colours, so two of the conditions prescribed had been complied with.

Mr. DEBENHAM was of the same opinion as the two preceding speakers.

Mr. TAYLOR said that one of his correspondents in Dublin arrived at the conclusion that Mr. Bewley knowing of the two gases being mixed in the bottle, proceeded to let them escape, forgetting that there was a light in the room, and the question was whether the ignition would extend into the remainder of the gases under pressure. Once Professor Piazzi Smyth had an explosion with the mixed gases, after which he (Mr. Taylor) tried experiments and found that the gases could be exploded through the grain of wood, also through a piece of tube several inches in length filled with the very small leaden shot known as "snipe dust;" through "Hemming's safety jet" the ignition would pass with the utmost ease.

Mr. J. J. BRUGESHAU said that once there was a small scratch in the slide of his gas engine, through which at last flame found its way; there was then a violent explosion, and the place filled with suffocating smoke.

Mr. TAYLOR described how, by means of a miniature gas bag attached to spiral springs, he had provided the means for sucking back the mixed gases while burning, so as to cause an explosion under desired conditions.

Mr. HADDON remarked that, as well as he remembered, an explosion travelled in mixed hydrogen and oxygen gases at a speed of one thousand eight hundred feet per second.

Mr. TAYLOR suggested that the meeting might pass a resolution to the effect that the two gases as now supplied commercially to the public in iron bottles are perfectly safe to use.

The HON. SECRETARY was of the same opinion, but that the bottles were not sufficiently distinctively marked; all the oxygen bottles ought to be painted one bright colour all over, and all the hydrogen bottles another bright colour all over. He had heard that not alone was this done in America, but the rooms in which the compressing was done at the works were painted all over of the same distinctive colour as the particular bottles to be filled therein so that if a bottle found its way into the wrong room the mistake was palpable at once.

Mr. W. H. HARRISON said that a mixture of oxygen and hydrogen could not be exploded all at once; the heat brought the force of dissociation into play, and some uncombined gases escaped.

Mr. HADDON, in the course of a short discussion on explosive mixtures which followed, said that once a man was pouring a few grains of fulminating silver from a bottle into his hand, and the resulting explosion blew the bones of his hand through the wood of the table.

Mr. TAYLOR spoke of the explosive properties of iodide of nitrogen, and observed that in the removal of photographic stains they should not be removed from the fingers by means of ammonia and iodine, the photographer was at no great distance from danger. Chloride of nitrogen was more dangerous still; he had seen a minute drop of it explode and indent an anvil. Some of these explosives were so violent that it was almost dangerous to utter their names, even in a whisper.

Mr. A. COWAN asked what was the best rule to adopt to photograph two heads to match each other as companion pictures, the one being that of a man with a bald head and great beard, the other that of a woman with an immense chignon towering high above her head. If they were done actual life size they would not look like pairs; the woman would look twice as big as the man in the finished picture, and the latter would look ridiculously small by comparison.

Mr. BRIDGE went by no measurements in such cases. He projected the two images side by side upon a screen, until their relative dimensions were such as to please him. He then exhibited to the meeting some heads enlarged to greater than life size, which he had taken upon Marion's bromide paper by means of the limelight, and a condenser with twenty-five seconds' exposure. He used the ferrous oxalate developer. The weather at this time of year was so bad, he said, that he often took portraits as well as made enlargements by the aid of the limelight.

WEST LONDON PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held at the Addison Hall on Friday, the 8th instant, the President in the chair, when Mr. J. D. ENGLAND read a paper upon *Flash Light Photography*.

The lecturer said that although he purposed giving them a demonstration on taking portraits by flash light they must not be led to suppose that he was *au fait* in portraiture, and that his experiments were principally confined to testing plates. He had, however, recently made many trials with the various flash lights, and believed there was a large field open to amateurs and professionals and a new source of pleasure to the lovers of photography generally. Two years ago Dr. Piffard, of New York, first announced the result of his experiments in this direction. He succeeded in taking instantaneous photographs by means of a mixture of magnesium powder and guncotton, and since that time, thanks to the improvements in the necessary apparatus, instantaneous portraiture had become possible under what would a few years ago have been deemed impossible conditions. The use of flash light photography had been invaluable in aiding scientific research. Julius Sach had obtained photographs showing the successive stages of the development of the buds and flowers of a certain cactus. In the studio it had also been of service to the photographer, for portraits were constantly taken evidencing the fact that good work could be done by its aid. The light might be obtained, firstly, as introduced by Dr. Piffard, by means of exploding a mixture of guncotton and magnesium; gunpowder might be substituted for the guncotton, but was not quite so effective; and, secondly, by using several expensive mixtures containing powdered magnesium as one of their constituents. These preparations, however, were of a dangerous nature, and the experimentalist should exercise caution in using them; and, further, where sulphide of antimony is used the fumes given off by combustion were very dangerous. With some samples of magnesium the lecturer was unable to obtain a flash; this occurred when old powder was used. The standard flash light as generally used was procured by throwing magnesium powder through a flame. The important feature of the production of the light was the size of the particles of powder, which ought to be as fine as possible, to insure perfect and sudden combustion. Sufficient attention was not generally paid to this point. Oxygen might be thrown through the tube instead of atmospheric air, but the advantage in doing so was not great. The quantity of powder necessary would vary, but five to ten grains was sufficient, with a rapid lens and a rapid plate, to produce a fully exposed negative. In portraiture the light should be placed high, to the right or left of the camera, at a distance of five or six feet from the sitter. The plate and lens should work as rapidly as possible, so that a small quantity of magnesium might be used, thereby shortening the exposure and not allowing time for the sitter to move the eyes. A great many articles on the subject stated

that the gas should be turned down before the exposure was made; this the lecturer thought to be a great mistake, and tended to produce a startled expression. A reflector or white screen should be suspended about two or three feet from the sitter on the shadow side, and if the sitter be placed four or five feet from the background a sharp shadow will be avoided. A good background might be improvised by suspending a woollen blanket, while a linen sheet would make a good reflector. If what he had said that evening resulted in inducing others to take up an extremely interesting department of photography which he had brought before their notice he should feel amply repaid for any little trouble he might have incurred.

At the conclusion of the lecture, which had been illustrated by many beautiful experiments, Mr. England exhibited a variety of flash lamps by James, Hinton & Co., C. C. Veyers, and Horne & Thornthwaite.

Mr. J. A. HODGKINS said, as the information might be useful to members, he would ask Mr. England which he considered the best form of lamp to use.

Mr. ENGLAND said there were many forms equally satisfactory, but, personally, he used Hinton's, which produced a large luminous flame.

Mr. HARGREAVES wished to know whether the fumes of burning magnesium were injurious to picture frames and similar articles.

Mr. ENGLAND thought no injury need be apprehended; any deposit could easily be removed with a light dusting brush.

Mr. F. W. HART then proceeded to give a description of his lamp and demonstrated its action.

The PRESIDENT then informed the meeting that Mr. Bonnetto had been unable to complete his promised paper in time for that evening; he had, however, very great pleasure in introducing to them a gentleman whose name was a household word among photographers—Mr. Warnerke, who was now on a visit to this country.

Mr. L. WARNERKE (who was received with enthusiasm) said when he received their President's request to make some communication to the new Society he had only just returned from Russia, and, consequently, he had not had leisure to prepare an elaborate paper for the occasion. However, he had brought with him a flash lamp which he had used many times on his journey, not knowing that the subject for discussion that evening was to be *Flash Light Photography*. The lamp was devised by a Russian gentleman (M. Gratcheff), and although it was not so elaborate in design as some which he had been shown, it was capable of doing good practical work. Its remarkable feature was its extreme portability. As they saw, it could conveniently be carried in the pocket. In shape it was like a small metal pill box about two inches in diameter, a small elbow tube passed through the side, to one end of which was attached a tube with pneumatic ball, the upright portion of the tube received the magnesium; the box was then filled with asbestos, and a disc of wire gauze completed the apparatus. Although the principle of this lamp was the same as many others, it had some special points; the quantity of magnesium required was extremely small—as much as would lie on the end of the nib of a pen was sufficient for ordinary purposes. This was a great advantage when using the lamp in a small apartment. Many lamps, on account of the quantity of smoke they produced, were very objectionable. Two lamps judiciously placed would be found to give the best results and would prevent heavy shadows. (Mr. Warnerke then, by means of a detective camera and two of his lamps, took a portrait of the President and the two Secretaries.) The speaker then exhibited another form of lamp with which a succession of flashes could be obtained without recharging. He said this lamp would prove very useful in photographing dark interiors and similar subjects where one flash would not give sufficient exposure.

The PRESIDENT inquired whether the flash light had been used for portraiture in Russia.

Mr. WARNERKE said it had already been used for that purpose. He considered that it would be an immense boon to the amateur, who had not often the means of properly lighting portraits and groups. He thought amateurs ought to derive greater pleasure from taking portraits of their friends, as in the future such photographs would prove to be of far greater interest as reminiscences than any landscape photograph. Mr. England had said that it was better to leave the ordinary light burning in order to avoid startling the sitter by the flash, but a little judgment on the part of the operator would avoid that. He had seen a theatrical group of about one hundred persons taken successfully on a 12 x 10 plate; the lighting was quite natural. Such an exposure could not have been made by daylight. Flash light preparations containing chlorate of potash were very objectionable and dangerous. When his firm were exhibiting at the late Exhibition at St. Petersburg a serious accident happened to one of his assistants, who, when operating with the powder, incautiously left the lid of the jar containing the mixture open, and the result was a serious explosion.

The PRESIDENT said it would probably be conceded that flash light photography was a most important subject, and one which deserved the attention of both amateurs and professionals, and he was gratified to see such a large attendance of members; he could say, without exaggeration, that the present was the most important meeting upon the subject which he had yet attended.

Mr. Hodge then exhibited a new form of lamp just introduced by Sands & Hunter, the design and workmanship of which were much admired.

On Friday, the 22nd instant, Mr. T. Stafford Hazen will read a paper on *The Autotype Process*. Visitors are invited.

CAMERA CLUB.

On Thursday Mr. J. E. Austin read a paper on *Enlarging*. Mr. E. Ferrero occupied the chair.

The lecturer illustrated his remarks by reference to large diagrams showing the operations with the solar camera, and daylight enlarging to the sky and to reflectors. Mr. Austin held that mirrors were greatly to be preferred to opal and white paper reflectors. He further exhibited a series of direct enlargements on Alpha paper enlarged from whole plates up to 30 x 24.

In the discussion which followed several members took part.

A detective camera sent by Messrs. Hinton & Co. was exhibited, also some enlargements sent by Messrs. Fry & Co.

The subject on Thursday, February 21, will be *Films*, when communications on the subject from Messrs. Tolley, G. Mansfield, H. H. O'Farrell, and Captain Barnes, will be read or given at the meeting.

LEWES PHOTOGRAPHIC SOCIETY.

An ordinary meeting of this Society was held at the Glee Room, Cliffe, on the 5th instant. The President occupied the chair.

The evening was devoted to a discussion on *The Making of Lantern Slides*, and some good slides by the President, and Messrs. Foxall, Conder, and Morris, were exhibited.

The President also showed some commercial slides for comparison with those of the members, and it was the general opinion that those of the members were equal to the others.

In the discussion on the developer the merits of both pyro and hydroquinone were put forward, but the latter seemed to find favour with most of the members.

On March 5 Mr. Foxall will read a paper on *Carbon Printing*, with demonstrations.

DEVON AND CORNWALL CAMERA CLUB.

A MEETING of this Club was held on the 6th instant,—Mr. R. Murray in the chair.

Mr. A. A. CANNELL gave a demonstration, *Contact Printing on Bromide Paper*.

He informed his audience that, as they were all aware, during the winter months great difficulty was experienced in printing on ordinary sensitised albumenised paper. The variations in daylight were such that on dark days the negative might sometimes be left in contact with the paper for considerable periods of time, with the frequent results of curious stains and markings, ruining the negative as well as the silver print. He intended, therefore, showing them a simple, easy, and cheap way of overcoming this difficulty by using bromide paper. Of this there were several varieties, and he had heard good accounts of, among others, those prepared by Eastman, Morgan & Kidd, Hunt & Thornton, Fry, &c. But he especially intended to bring to their notice two papers prepared by the Ilford Company. These were Alpha and Ilford slow bromide. He produced two negatives; one dense, the other thin but full of detail, and he purposed making two prints from each negative on both Alpha and Ilford bromide; developing one set with ferrous oxalate, and the other with hydroquinone and caustic potash. He had only tried the latter developer for the first time a few days back, but he already much preferred it to any other. The gas having been turned down, the lecturer proceeded to give exposures, varying from four seconds for the slow bromide paper under the thin negative, to thirty-five seconds for Alpha under the dense one. These were successfully developed, the general opinion being in favour of hydroquinone. In reply to questions, the lecturer stated that he thought printing on bromide paper during the winter months quite as cheap as by the ordinary way on silver paper, taking into account the damaged negatives and spoilt prints occasioned by the latter process. With the Alpha paper, which he strongly recommended, one could get any colour, from dull olive green through pink to black, by varying the exposure and toning, which latter could be done at leisure after development. The hydroquinone could be used five or six times, and thus an entire batch of prints could be developed in the same solution; he therefore considered it cheaper than any other developer.

Some conversation took place as to the possibility of making experiments with the magnesium flash light, and it was eventually decided to hold a meeting for that purpose on the 29th instant; a committee being appointed to make the necessary arrangements, provide draped models, &c.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

THE usual fortnightly meeting of the above Society was held in the Institute Bealey, on Friday, February 8. The President, Mr. Pringle, in the chair.

Messrs. Clare and Denipsey were elected members of the Society.

Mr. Hawkins exhibited some photographs taken with a hand camera.

Mr. Reeves showed negative and prints.

Mr. Pringle showed some specimens of a new variety of collotype printing. They were characterised by extreme sharpness and delicacy of detail.

Prints to the club album were contributed by Messrs. Pringle, Hawkins, and Jones.

Mr. PRINGLE then continued his address on *Practical Photography*, this time referring to various printing processes. In the course of his address he compared the relative merits of platinum and bromide printing, and maintained that as good results could be obtained with the latter as with the former. Not only this, but bromide had one great advantage over platinum, inasmuch that weak negatives properly managed would give good prints, an impossibility with platinum.

The next meeting, on the 22nd instant, will be a lantern evening.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held on February 6,—Mr. President Andrews in the chair.

The most important business for consideration was the question of the formation of a lantern section, and Messrs. Sturmer, Ambrose, and Dew (Secretary), were elected a sub-committee to take charge of the lantern work of the Society. With a view to putting the section on a working basis, and increasing the interest taken in this branch of photographic work, it was

decided that at the next meeting an exhibition of slides by the members should be held, to which friends should be invited.

Mr. W. D. WILSON then read a paper on *The Lantern at Home*. He commenced by briefly recapitulating the manipulations necessary for the production of the slides, and, treating the subject in a humorous manner, went on to describe how the optical lantern could be made the means of giving amusement, pleasure, and instruction combined, at a family or other evening party, laying particular stress on the necessity of keeping the audience and spectators interested, which could be done by an adroit mixture of fact and fiction in the narrative. Slides illustrating "Child Life," "Scenes on a Farm," and other subjects treated in the paper, were shown on the screen.

Some slides by Messrs. Ambrose, Owen, and Dew, were then shown, a group of the officers of the Society for last year, by the last-named, being received with applause.

After discussing and answering the queries found in the question box, the meeting terminated.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of the Association was held in the Philosophical Society's rooms on the 7th inst., The President, Mr. William Lang, jun., F.R.S., in the chair.

The minutes of last meeting having been read and approved of, Messrs. W. A. Bryson, W. J. Finlayson, George S. Henry, William B. Smith, H. M. Breche, H. McDowall, and A. Bulloch were admitted as members of the Association.

THE PRESIDENT spoke of the loss the photographic world had sustained in the death of M. Buissonnas, of Geneva, whose instantaneous photographs of children attracted so much attention in the International Exhibition.

THE SECRETARY then read the report of the proceedings of the Society during last session. On the whole this was considered satisfactory. The roll showed an increased number of members, and the papers read had been of most interesting and varied character.

The Treasurer's report was also read.

It was decided to have the reports printed.

MR. LANG then read his paper entitled *Fifty Years' Photography, 1839-89*. This was illustrated by a series of lantern transparencies, among which were portraits of Porta, Niepce, Daguerre, Sir Humphrey Davy, Talbot, Mungo Ponton, and Sir John Herschel. The lecture was also illustrated by a number of old and rare books by Porta and others, which Mr. Lang exhibited. As the paper proved to be of considerable length the second portion of it was held over till another meeting.

A series of lantern transparencies were shown on the screen, and a number of specimens of Lichtdruck printing were also exhibited.

SOCIETY OF AMATEUR PHOTOGRAPHERS OF NEW YORK.

REGULAR monthly lantern slide exhibition. The Committee on papers and publications send us the following report:—

The exhibition took place on Friday evening, January 25, at the rooms of the Society, 122, West Thirty-sixth street, and was largely attended, there being as usual a great many ladies. The first half of the exhibition included about sixty slides contributed to the American Interchange by the Philadelphia Amateur Photographers' Club, and represented the work of twelve different members. The work of this Club is much superior to that formerly exhibited. A brief intermission followed, then about fifty slides made by members of our own Society were shown. They represented various subjects, in style of views near and in New York.

The lantern slide Committee has under contemplation the collection of a special set of slides illustrating *Interesting and Picturesque New York*, and asks the aid of members in furnishing slides.

Correspondence.

Our Correspondents should never write on both sides the paper.

SPOTS IN NEGATIVES.

To the Editor.

SIR,—I send you a negative which has been ruined, as far as I can tell, by magnesium powder. When I placed the negative in the fixing bath there were no spots or stains on it. Being at a loss to know what had occasioned them I examined the bath and discovered several specks in it, which I concluded must be magnesium; so looking to the vessel containing the hypo crystals, I saw that it had been lying uncovered close by where I had been working and experimenting with blow-through lamps; consequently, some of the unburnt powder had fallen on the surface of the hypo, and then been carried to the bath.

In subsequent research I found that about half a grain or less of magnesium powder in six or seven ounces of hypo solution after fixing leaves a thick muddy precipitate. Perhaps some of your readers will be able to throw some light on the subject.—I am, yours, &c., ALBERT URE.

Hope Park, Bonnybridge, N.B., February 6, 1889.

[The spots are owing to a reduction of the silver in the hypo bath, caused by the particles of magnesium.—Ed.]

RA. BRIGHTON PHOTOGRAPHIC SOCIETY.

To the Editor.

SIR,—I think some explanation is due to the professional photographers who, through my instrumentality, joined the Society in question. Some

time ago I conceived the idea that a photographic society or club was a Brighton necessity, and you, Mr. Editor, are aware of the steps I took towards this object. I called on many amateurs and professionals, and got promises of support from nearly all of them, when I afterwards found some one else attempting to form a society. I immediately called on him, and heard partly what had been done. I then threw in all my energy with them. I spent two days in canvassing. I informed each candidate that he would receive an invitation to the next meeting, which would take place on the 7th instant. Mr. W. H. Rean, the Secretary *pro tem.*, did not send those gentlemen notices, "as," he said, "they were not elected." Now my idea was that no regular society had existed previous to the meeting which took place on the 7th (see note enclosed on the form of application). Judge of my surprise, when attending the meeting on the 7th, to find that the rules had been drafted, and were to be discussed and finally disposed of at once. I proposed, and it was seconded by Dr. Dawson, "that these rules be submitted to all the members, at a meeting called for that purpose, for their approval." An amendment in opposition to mine was carried by a majority of eight to five out of a total of seventeen persons present.

I am supposed to be an original member, although I was not called to attend any meeting before the 7th. I presume I was invited out of courtesy, and I thank those gentlemen, whoever they may be, for the honour. I was told that the Brightonians were "critical;" no, let me give it the proper name—"cliquish." Per example, a well-known gentleman, who in one breath told me he was not the least proud, the next moment said he would not sit beside one of the gentlemen interested, as he was his inferior in intelligence. I took the trouble to look up the Medical Directory, and I find that the gentleman of "inferior intelligence" has one more qualification than the other. But the truth leaked out—one was a homoeopathic practitioner. I explained in vain that the Society was not a medical one. The intelligent individual was cornered when I asked him if he could or would get up a society where the subscription would be at from 2l. 2s. to 21l., as he objected to the annual subscription of 5s. and that beach photographers would be eligible. I draw the line at the beach. Oh! ye fellows of the Royal Society, why do you not come to Brighton to fill your ranks, where there are men of such broad and liberal views? I sincerely hope that, in spite of these extraordinary proceedings of the Society, it may be useful and successful in every way. I have promised, and will do my level best for it, although personally it will not help me much, as it is "Open Sesame" to me with all the professionals.—I am, yours, &c., A. L. HENDERSON.

Argyle Mansion, Brighton.

P.S.—Of course, when the rules of the Society are published, members can retire or have them altered. I asked if they provided for an emergency that might occur, viz., the leaving of the chair by the president, and the resignation of the council.

[The circular enclosed reads as follows:—"The Opening Meeting of the above Society will be held at 36, Vernon-terrace, on Thursday evening, February 14, at 8.30 o'clock.—Faithfully yours, W. H. Rean, Hon. Sec. (*pro tem.*) Agenda: Election of Officers, General Business."—Ed.]

VIENNA SCHOOL OF PHOTOGRAPHY.

To the Editor.

SIR,—Last year, during a visit to the principal photo-mechanical establishments of Germany and Austria, I spent a week at the Vienna School, and in answer to "G. A. Grove" in your issue of February 1, forward answers to the inquiries.—1. The school is open to ladies over eighteen years of age. 2. It will reopen in February. 3. Certain classes can be joined at any time. 4. The terms depend upon the classes the pupil attends.

I can give "G. A. Grove" every particular with regard to the classes, fees, &c., if communicated with direct.

I should also be pleased to communicate with "Mechanic" who wrote you last week.—I am, yours, &c., EDWIN C. MIDDLETON.

Stannmore-road, Birmingham.

PHOTOGRAPHING IN NORWAY.

To the Editor.

SIR,—Your correspondent "Aliquis" will find no difficulty whatever in sending on parcels of plates or anything else in Norway from place to place. I have travelled and photographed, during the past four years, over the greater part of the country, and never experienced the slightest difficulty in having parcels sent to any places where the steamers touch. In fact, I once left three dark slides in an hotel at Vik-i-Eidfjord, and they followed me all over the country, and I finally found them safe and sound here on my return home. "Aliquis" need only address his plates to himself at whatever hotel he intends calling at, and leave the parcel at the steamship office in Bergen or wherever else he may happen to be, and he will find it safe in the hotel-keeper's charge on his arrival. If he goes to Mr. Bennett, either in Bergen or Christiania, he will send anything anywhere to await his arrival. The charges for sending parcels by steamboat are ridiculously small. I sent a portmanteau, which I did not

wish to take with me across the country, all the way round from Bergen to Christiania for the insignificant sum of 5d.!

Almost all the hotel-keepers and the captains and stewards of the coasting and fjord steamers speak English, so on the main routes "Aliquis" will experience very little difficulty from not being acquainted with the language; but even in out-of-the-way places, where travellers seldom go, he will find that he will get on capitally with the natives if he takes with him a copy of *Bennett's Phrase Book*.

As one who has taken hundreds of negatives, both on plates and paper, in Norway, I would suggest to him that if he wants to photograph the country with ease, comfort, and rapidity, he should take with him an Eastman's roll-holder, and use the stripping film.—I am, yours, &c.,
St. Leonards-on-Sea. A. M. MacDONA.

To the Editor.

Sir,—In reply to "Aliquis" (*THE BRITISH JOURNAL OF PHOTOGRAPHY*, page 95, February 8, 1889), little encouragement can be given to any idea of sending on plates in advance with practical advantage in Norway. In illustration whereof the following anecdote sets forth alike the honesty of the Norwegians and their want of organization. A traveller sent his luggage by sea, say from Molde to Christiania, whilst he travelled overland. Six months passed away and he saw nothing of the luggage; but on sending a friend to investigate, the luggage was found still on the deck of the steamer on which it had been placed at Molde, where it had remained, travelling up and down the coast, as safe as possible but undelivered.—I am, yours, &c.,
February 8, 1889. G. A. K.

TWO WAYS OF DOING BUSINESS.

To the Editor.

Sir,—Some time ago an amateur brought me a pretty little quarter-plate camera of the pocket type and asked me if I would examine it, as do what he would he could not get a picture with it, good, bad, or indifferent. I tested it and found that a negative could only be secured by removing the instantaneous shutter with which it was fitted, and giving an exposure of two or three seconds. I advised the amateur to return it to the makers for examination and report, as the fault seemed to be with the lens. This he did, and shortly afterwards received a note from the firm stating that the camera was all right, and that he need not trouble any one about it as they had sold it to a gentleman who was going abroad. I pity the purchaser! Contrast this with the following: Last summer I sent a quantity of residues to be reduced, and in due time received a cheque for an amount considerably less than I anticipated it would be, but thinking it was owing to the depreciation in the value of silver, and having confidence in the firm, I duly acknowledged the receipt of the cheque and then the matter ended, as I thought. Early this year I received a note from the firm stating they had discovered an error in my account, enclosing a corrected one with a further cheque of over three pounds as due to me. No comment is needed.—I am, yours, &c., W.

SORTING LANTERN SLIDES.

To the Editor.

Sir,—Having read Mr. York's letter on the above subject, I should like to say a word in reply. Even since I commenced to make slides I have used a red-surface paper for binding; on each mask I have placed two spots, and on each spot an initial with indiarubber-faced type, consequently they have been sorted instantaneously. There are an immense number of tints to be procured; they are easily gummed in the sheet, ruled, and cut to size afterwards. Supposing two persons happened to have the same tint, the initials would rarely be the same. By Mr. York's plan the face of each slide must be examined, i.e., if the black binding continues in general use. If the number could be placed securely on the edge, in my opinion it would be far more convenient to sorters. I am glad to see several members of the Photographic Club have adopted the coloured binding, and have found the benefit of it when the show is over and they want to catch a certain train.—I am, yours, &c.,
Colebrook, North Finchley, N. LEWIS MEDLAND.

THE PHOTOGRAPHIC CONVENTION.—A DEALERS' SECTION.

To the Editor.

Sir,—May I suggest for the consideration of the Convention Council the advisability of forming a dealers' section, and allowing them an opportunity of discussing photography from their point of view upon one or more occasions during the meeting in London in the forthcoming summer? There are many matters of importance to the trade which require careful and united consideration, and where can a better opportunity present itself than at the Photographic Convention of the United Kingdom?—I am, yours, &c.,
20, John William-street, Huddersfield. HERBERT M. SMITH.

COMPRESSED GAS IN CYLINDERS.

To the Editor.

Sir,—My remarks on this subject, written last week end and posted on Monday morning, were, as stated, based upon the information which had appeared in the newspapers. But this morning (Wednesday) I have seen (for a few minutes only) a report of the official inquiry into the "Dublin explosion," wherein it is stated, as a fact beyond doubt, that the explosion was not due to excessive pressure, but to the use of mixed gases in one cylinder (mixed with a full knowledge and intention by Mr. Bewley himself).

I also read in the report a statement to the effect that the Brin Oxygen Company supply oxygen in black cylinders and hydrogen in red cylinders; but this is not an absolute rule, for personally I have had a dozen black cylinders containing hydrogen for one red, and I maintain that where there is no absolute rule there is liability to mistakes.

I also read in the same report the suggestion which I made advocated by one of the professors engaged in the inquiry, i.e., to make the screw necks of the oxygen and hydrogen cylinders of a different size.

However, a full report of the inquiry has doubtless reached the office of this JOURNAL, and will be published in the next issue. But, as already stated, my article was written before I had seen the report.—I am, yours, &c.,
W. J. CHADWICK.

February 13, 1889.

Exchange Column.

* No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Will exchange silver watch, "Boston lever," for 5x4 rapid rectilinear.—Address, ROBINSON, Photographer, Abertillery, Mon.

Will exchange C.D.V. by Janin for good half-plate landscape camera.—Address, C. E. BRIDGES, 594, Harrow-road, London, W.

Wanted, half-plate camera, one or more double slides, tripod, with or without lens; exchange, silver lever hunter, cost 6l.—Address, S. TAYLOR, 140, Battersea Park, Battersea Park.

Dallmeyer's quick-acting stereoscopic doublet, special, for views and portraits; wanted, whole-plate wide-angle rectilinear, by name or Ross. Difference adjusted.—Address, WATSON, Oakland-road, Hanwell, W.

Will exchange good cabinet burnisher, by Veyers, for whole-plate doublet standard slide and carrier, or whole-plate and half-plate ditto. Must be sound and light.—Address, BOWEN, Photographer, St. Germans, Cornwall.

A 12x12 Dallmeyer studio camera, vertical and horizontal swing back, Spanish mahogany, endless screw, &c., will be exchanged for rapid rectilinear of six inches focus, any make.—Address, R. H. HUGHES, 3, Boley-hill, Rochester.

Will exchange 12x10 folding camera, three holders (single), and Dallmeyer's rapid rectilinear lens (together or separate), for backgrounds, accessories, or optical lantern and burnisher.—Address, HENRY BROTHERS, The Spot, Derby.

For exchange, James's triple flash lamp, Marinn's embossing press for cabinets and cards, four dies, cushion, and oval, two backgrounds (one interior, one exterior), Cowan's changing box for 10x12 plates and under, two large glass dipping baths; wanted, tricycle by good maker.—Address, THOMAS WERN, Prospect, Swindon, Wilt.

Answers to Correspondents.

* Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

T. B. HICKS.—Thanks.

W. A.—Box of negatives received. Thanks.

WRIGHTS.—Your weights will do well enough.

URANIUM.—A personal interview would be necessary.

VICTOR.—We do not know, but inquiry will be made.

ROBERT STEWART.—Hart's lamp will answer the purpose.

EAGLE.—The articles will probably be reproduced in book form.

J. C.—Your picture is very good for a beginner, its chief fault is over exposure.

J. C.—You may use either of the developers on pages 625 and 629 of the ALMANAC.

R. V. D.—The silver stains cannot be removed without ensuring the destruction of the negative.

TEX ERY.—You will find a description and drawing of the shutter you mention in our volume for 1861.

- INK.**—See our *ALMANAC* for the present year, page 638, where you will find the particulars for making the ink for rubber stamps.
- A. A. A.**—Excellent photography, but totally wrong in the placing of the background. The horizon is two and a half feet lower than it ought to be.
- OMMA.**—Methylated spirit can be decolorised, but the excise laws will not allow it to be done. The methyl does not interfere in any way with the varnish.
- M. WILSON.**—Inks and varnishes suitable for photo-lithography may be obtained from Messrs. Hughes & Kimber, Fetter-lane, or from Winstone, Shoe-lane, E.C.
- ROSE** inquires how some red pictures she has seen on "porcelain" are made? They are made by the carbon process in the ordinary way, using a tissue containing a red pigment.
- O. N. M.**—Muffle-furnaces, suitable for burning-in enamels, are supplied by Messrs. Boulton & Co., Lambeth. Messrs. Fletcher & Co., Warrington, also supply them. The latter firm has a form to be heated by gas, which is very convenient.
- A. M. M.**—The crystalline marks on the negative are due to hyposulphite of soda, which, from insufficient washing, has been allowed to remain in the film. No articles have been written on this subject, but the same story has often been told in this column.
- PERFUMED** cannot get his gelatine plates dried free from dust, and asks for a cheap means of drying them in a box into which the air can be filtered.—One method of effecting this is to set the plates in a box of which two of the sides are composed of a cotton fabric.
- JACOBS** asks if when we undertake the registration of photographs we necessarily publish the fact, and if so, in what papers? also the cost?—Reply: By sending 1s. 6d. to our publishers any picture will be immediately registered, and notification thereof made in this column.
- BRITISH.**—In fitting your new studio, have two sets of blinds, both fitted on spring rollers, one at the top and the other at the bottom. In this way you will be able to secure any effect of light. The American photographs that you so much admire were taken in a studio fitted in this manner.
- A. WIGWAM** asks if there is any negative varnish that can be poured on the plate while it is cold without its chilling as it dries, and if so, how is it made?—Dammar varnish, that is, dammar resin dissolved in benzole, may be applied cold. From ten to fifteen grains of the resin in each ounce of the solvent is a good proportion.
- J. C. (York)** inquires how he can get ordinary water colours to adhere to albumen prints. He says that the surface of the paper repels the colour as if it were greasy.—If the surface of the picture is highly repellent, a little dilute oxgall washed over the picture will cause the colour to "take." Lacking the surface with the tongue is also a remedy.
- A. Z.** says: "On adding the iron solution to the oxalate of potash solution it at once becomes turbid and brown, instead of remaining clear, as I am told it should do." He asks the reason.—The reason is, probably, that too much iron is added for the quantity of oxalate present. The latter solution should be a saturated one. Either strengthen the oxalate solution or use a smaller proportion of iron solution.
- H. K.** writes, asking: "Will you please inform me whether, after making an application for a patent, one is deterred in selling the article from the date of such application or whether it is necessary to wait till the patent has been sealed?"—In reply: The sales may be commenced as soon as notification of acceptance of the provisional specification has been made, although, when convenient, it is better to defer this until the final specification has been lodged. The protection, however, commences with the date of the first application.
- A. V. Z.—1.** Equally as good and permanent results can be obtained with gelatino-chloride as with gelatino-bromide plates. It is merely a question of manipulation.—2. Try B. J. Edwards, The Grove, Hackney, E.—3. It is desirable that the camera should have an extension twice the focus of the lens, as this enables you to copy a picture its own size. Numerous advertisements of extra long focus are to be found in our *ALMANAC*.—4. We can give no estimate of the weight the camera ought to be; no two of ours are alike in this respect.
- G. BACKHAM** complains that, recently, when he took some prints out of the fixing bath and put them into water they suddenly became covered with small blisters. He wishes to know the cause, as he has never seen anything like it before. The paper employed was ready sensitised, double albumenised.—If our correspondent has never met with this experience before he is certainly very fortunate, as most workers are more or less familiar with it. The best way of avoiding the difficulty with paper which blisters is to have the fixing bath the same temperature as the washing water, and, instead of transferring the prints direct from the hypo into the water, to first immerse them in a weaker solution. Blisters, with some papers, are generally formed when the prints are suddenly transferred from a dense solution into plain water.
- MRS. WILSON** writes: "I have a toning trouble. I use ready-sensitised paper which prints nicely and tones well, but on immersion in the hypo the prints turn to the well known unpleasant brown and remain so. I have tried hypo of different strengths, and immersion of different lengths, with much the same results. Can you assist me?"—2. A shop window I have steamed so much when the gas is lighted as to render the goods almost invisible. Have you a remedy?"—In reply: 1. Probably the toning has not been carried to a sufficient extent. There are many sensitised papers which tone with great difficulty; one such sample on which we experimented lately was found, by the simple act of fuming with ammonia, to acquire very rich purple tones.—2. To prevent your shop window from steaming, try the effect of rubbing it over with glycerine and then very nearly wiping it all off. This is said to prove a remedy.

A WOULD-BE AMATEUR asks: "What is the cost of a complete set of photographic apparatus for taking pictures?"—A "complete set" may be had from one guinea to several hundreds of pounds. Without knowing the size of picture required, or the quality of apparatus desired, it is impossible to answer such a question as this. Our correspondent had better obtain catalogues from some of the houses whose advertisements appear in the columns devoted to the purpose.

NOTTINGHAM AMATEUR PHOTOGRAPHIC ASSOCIATION.—Last Monday evening a smoking concert was held. A large programme was gone through, and a most enjoyable evening spent.

ROYAL SCOTTISH ACADEMY.—On Monday, at a general meeting of the Royal Scottish Academy, held in Edinburgh, Mr. William B. Hale and Mr. Robert McGregor were elected academicians, in room of the late Mr. Robert Herdman and Mr. Norman Macbeth.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting, February 20, will be on *Lantern Matters*. This is a lantern night instead of the 27th, which will be devoted to the exhibition of photographs by the members and the reading of a paper by Mr. W. Cobb.

PARIS UNIVERSAL EXHIBITION, 1889.—In response to an urgent appeal from Sir Frederick Leighton, the Chairman of the Committee, over 9000 have been subscribed for the Fine Arts Section, and it is hoped that this amount will be largely increased by private liberality. The Council of the British Section have also set aside from their general revenues a sum of 15000. for the Fine Arts, so that there is at present between 21000. and 25000. available.

LIMELIGHT EXPLOSION AT AN ENTERTAINMENT.—The other night, during the performance of the pantomime "Robinson Crusoe" by the members of the Chorley Amateur Dramatic Club, in the Town Hall, Chorley, Lancashire, the limelight apparatus exploded. The gas lights were extinguished, and a panic ensued among the audience, children screaming and great excitement prevailing. A rush was made for the doors, and it was a wonder no one was hurt, but Mr. H. N. Whittle and other officials promptly appeared on the stage and calmed the audience, and the performance was resumed. The only damage done was the smashing of several plate-glass windows.

THE ARCHBISHOP OF YORK ON RETOUCHING.—Speaking at the Sheffield School of Art *conversazione* on February 12, on "modern art," his Grace remarked.—In the shop windows, nowadays, one saw the portrait of an elderly statesman, who in reality had furrows on his face, which were the wounds of life's battle, the marks of victories won and conflicts gone through; but the photographer took out all the wrinkles, and touched up the negative, until at last the face was reduced to the condition of something boiled. He (the Archbishop) declined to part with the wrinkles—(hear, hear)—they were the character of the man; and he really thought there should be some protest against the misuse of this power of the photographer to retouch his pictures; but as long as there were mothers, and children, and wives, the protest would never be made, the wrinkles would still be objected to, and we should go on paying for what we vainly supposed must be real, because in a photograph, while there was not a square inch of truth in any part of it.

LIVERPOOL AMATEUR PHOTOGRAPHIC SOCIETY.—A highly successful move has been made by the members of the Liverpool Amateur Photographic Society in securing a local habitation of their own. A name they have already. The members are reasonably proud of the fact that theirs was the first strictly amateur photographic society established either at home or abroad. With advancing years the Liverpool Society apparently grows in health and vigour. Under its auspices was held last year probably the most successful all-round exhibition of photography yet witnessed. A very handsome surplus was derived therefrom, and the members of the Society feel now justified in establishing themselves in comfortable club quarters, instead of having merely, as heretofore, a place of meeting for one evening each month. In future the members will be able to fraternise daily, to consult their library and periodicals any afternoon or evening, and moreover to enjoy facilities for carrying out special photographic work such as have not previously been at their disposal. In their new club premises in St. George's-terrace North, they will be able to do their work of development, to change plates, to use the big club lantern, and to give demonstrations. In addition, the members, of course, will have the pleasure of more frequent social intercourse, implying a plentiful exchange of ideas, a comparing of notes, and a general strengthening of the bonds uniting the Society. The "comfortable quarters" in Colquitt-street, which some of the members are spoken of as leaving with regret, were only visited for a few hours once evening in each month, and the Society never in any sense had a home there such as it will in future possess. So popular, indeed, has the new move proved, that there has been a considerable increase in the Society's roll of membership, and the body promises to become more than ever qualified to maintain the reputation of Liverpool in the photographic world.—*Liverpool Daily Post*.

NOTICE.

ALTHOUGH we have given eight columns extra of text matter this week (forty columns in all), yet have we been compelled to leave over many interesting and valuable articles which we hope to overtake in our next.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1503. VOL. XXXVI.—FEBRUARY 22, 1889.

PYRO DEVELOPERS *VERSUS* GELATINE PLATES.

Those who have worked at photography continuously since Mr. Bennett first showed what potency for rapid work was the possession of gelatino-bromide—his negative of a lady pouring water from a jug is of historic interest—will have noted the gradual alteration which has taken place in the characteristics of the solutions recommended as the best for developing the plates of the period. In those early days, weak developers with little or no bromide were first introduced, to be superseded in turn by developers of considerable strength, and containing larger proportions of bromide, which again are gradually giving place to solutions of more economical character, from the paucity in the amount of pyro made use of. We believe that the platemakers themselves have not thoroughly taken their proper place in regard to *ex cathedra dicta* as to the best developer to use. Many plates have been issued with printed instructions for development, which, with the particular plate, were a complete farce to those who knew how to test them, and yet when suitably treated the negatives were not to be surpassed. A manufacturer ought to know, often does know, but not infrequently is ignorant of the best mode of treating the plates he makes. We make these preliminary remarks that our own observations may not be rejected untried on account of their opposition to some makers' own formulæ, though, unfortunately, the ridiculously intricate way in which these formulæ are put together renders any ready comparison of one with another entirely out of the question, until a number of compendious calculations have been made. We do not intend to let this particular absurdity retain its rampant absurdities without continual protest.

Taking now the strength of pyro, we find various proportions, running from about one to three grains per ounce, while the bromide present also varies considerably. The ammonia, most important of all, is recommended in proportions varying from about one minim to three per each grain of pyro, which mode of representing in a comparative manner the amount of this chemical present is the only correct one.

Now we unhesitatingly say that in a very large number of cases, if the stated amount of ammonia be employed, the best class of results will not be obtained; and, further, that if such quantities as recommended as a maximum be used, the plates in every respect—brilliance, rapidity, density—will be inferior to those treated with a smaller proportion of ammonia. Our present remarks, it is to be noted, bear only upon development with pyro and ammonia with sulphite; the fixed alkalies we do not now treat.

The true function and working qualities of ammonia in the developer are frequently not realised in practice, and as fre-

quently not understood. It was a long time before the majority of workers found that an important mode of obtaining extra density was to be found in increasing the proportion of ammonia used. Stronger pyro was, at an early date, recommended, and more bromide added to the developer was also said to confer additional density; but it was rare to find ammonia credited with this power. To this day large numbers of workers are ignorant of the part that ammonia plays in this connexion. Are we to account for this by the outrageous amount of ammonia some makers' formulæ contain, and the consequent working at a maximum itself erroneously great, preventing a due conception being obtained of the controlling power possessed by this alkali? Be this as it may, every photographer ought to be aware that greater variations in the density can be obtained by the addition of ammonia up to a certain point than by any other means.

This being thoroughly understood, we are about to make an observation that will be almost paradoxical. We call especial attention to the fact that with many modern plates the addition of ammonia beyond a certain proportion very largely interferes with the attainment of density, and, so far from assisting to force, as it is termed, an under-exposed plate, it has the very opposite effect when that limit is passed. The usual plan during development, when under-exposure is signified, is to add more and more ammonia, and this is quite right, as we say, up to a certain point; beyond that point it will produce not the anticipated effect, but an opposite one. We cannot, at the moment of writing, call to mind one single paper in which attention has been drawn to these two points—first, the over-stated maximum of ammonia to be permitted with many brands of plate; second, and most important, the greatly injurious effect as regards density and rapidity that an excess of ammonia will produce. Stress was laid upon this subject in a communication by a professional photographer of our acquaintance, who uses a very large number of plates in a year, and in the plates he sent us, and in others tried with the like object in view, the makers being among the foremost for quality and price, the effect of adding ammonia in preventing the attainment of density, in injuring the character of the image (apart from questions of fog), and, finally, the rapidity, was unequivocal and incontestable.

EXPOSING TRANSPARENCIES.

Much attention is devoted on all sides to camera exposures, that is to say, rather, to negative exposures, but comparatively little appears to be given to the exposure of transparencies, whether made by contact or in the camera. The

carelessness or apathy exhibited in this respect does not extend to other kinds of positives produced by development, such as bromide prints upon paper or opal—for the reason, probably, that any serious departure from the proper time of exposure makes itself clearly palpable at once, either in over-powerful contrasts, or in flatness and heaviness of results.

Now, with a transparency there is, so to say, no standard with which to compare the lights. A print upon paper or opal has the necessary standard in the colour of the support itself, and the eye naturally and instinctively ranges the gradations of the image alongside this standard. In the transparency, however, this standard is, if not entirely absent, at least replaced by another of a less reliable character, namely, the highest lights of the picture itself, from which all other values have to be taken.

Like a print on toned paper, a transparency may present to the eye, when examined alone, the most perfect gradation, and convey altogether a satisfactory impression, though its highest lights are represented by a veil of some density; but if such a print be compared with another from the same negative, in which the lights are represented by clear glass, the difference will be so marked, and so greatly in favour of the latter, that the beauty of the first will entirely disappear.

There are, of course, transparencies and transparencies, or rather there are different purposes to which the transparent positive can be put—as, for instance, for lantern slides, for window or other decorations, and for stereoscopic pictures, each and all of which permit of, if they do not require, different treatment. Take the lantern slide, for instance; here we require absolute transparency in the highest lights, and a delicacy and translucency in the general gradations that alone give it its value for the particular purpose to which it is to be put. For hanging in windows, or for framing in screens or lanterns, or other decorative purposes, the same transparency of the lights is desirable in order to sustain that sparkle that gives the great charm to a transparency; but the general strength or density must be greater. For stereoscopic work a result similar to the last is equally effective, but for this purpose the absolute “clear glass” lights are not so firmly to be insisted on, since a very faint veil gives a softness and solidity to the combined picture that are scarcely secured with slides possessing greater “sparkle.” Here, however, much must, of course, depend upon the subject, and we are far from recommending indiscriminate veiling as a means of securing artistic effects.

How best to secure the precise qualities required in a transparency, for whatever purpose required, should, therefore, be the study of all who practise this branch of the art, though—except, perhaps, in connexion with lantern slides—too little attention is given to the matter. Exposure is, of course, an all-important point in the calculation, far more important, indeed, than many even “old hands” recognise. In negative work we are accustomed to claim the advantage of more or less “latitude” of exposure, as it is termed—that is to say, of committing more or less error in the calculation of the time, without suffering to any great degree for the offence. But where the operator makes a practice of availing himself of this power or latitude, it is almost certain that the character of his work suffers, and that if he were to expend a little more care in timing, his general results would be of better quality.

Where transparencies are in question, however, the case is quite altered, for the so-called latitude almost disappears where

the very highest class of result is expected. Latitude does exist, truly, as in the case of negatives, but only in connexion with inferior results, either harsh in contrast from under exposure, or, what is more likely, heavy and wanting in sparkle from the reverse.

With gelatine plates the general fault is almost invariably that of over exposure, whether in the camera or by contact in the printing frame, for it is difficult to get some people to credit the exquisite sensitiveness of such plates to direct white light. With collodion films, however, the tendency is in the opposite direction, owing to the wide difference in comparative rapidity between the two classes of plates; but with collodion, fortunately, there is sensibly more room for varying the exposure, so that it becomes possible to *fully* expose within reasonable limits without overdoing it.

It is in camera printing that under exposure is most likely to be met with, since, even to gaslight, collodion films are sufficiently sensitive to enable a full impression to be obtained in a reasonable time. In camera work, therefore, with such plates, we should always counsel an exposure of at least a little more than is judged to be absolutely necessary. A difference of twenty-five or thirty per cent. in excess of the really accurate time will do no harm; in fact, in a bad light, two or three times the proper exposure will often not ruin the picture, where, with gelatine, the case would be hopeless.

In printing by contact by gaslight there need be little fear either of under or over exposure, nor any difficulty in calculating the time, since the latitude is sufficient to cover any reasonable error with this most convenient form of lighting. But if daylight or magnesium be used, then the danger of over exposure is magnified, and especially if thin negatives are employed. In such cases it is desirable to expose at as great a distance from the light as convenient: from the far side of a room, opposite a window if daylight is in question, and some feet from the flame in the case of magnesium. With very thin negatives, as an additional precaution, a sheet of ground glass or tissue paper may be laid over the frame.

In the Royal Commission, now sitting, photography is being more extensively made use of than in any previous proceeding in the Law Courts. Indeed, photography may be said to be largely instrumental in originating the Commission itself. The copies of letters which appeared in the daily papers in the first instance, and which gave rise to so much controversy at the time, were all printed from phototypic blocks. All the most important documents which have been produced in Court have been, or are to be, reproduced by photography. A number of photographs of signatures—genuine or otherwise—mounted in juxtaposition are much more convenient for comparison, or reference, than when they are on separate pieces of paper.

When photography is utilised, as it frequently is, in the detection of forgeries or tamperings with documents, a more pronounced result may often be obtained by copying the writing by transmitted light. By this means erasures, or chemical manipulation with the ink, will often be rendered more palpable in the photograph than when the negative is taken in the usual manner. In all cases of suspected forgery by erasure, or chemical means, two negatives should be made; one by a strong transmitted light, and the other by reflected light. Results may sometimes then be secured in one copy which are not discernible in the other, and *vice versa*.

SOME little time back we alluded to the fact that a large number of photo-mechanical prints had been arrested by the Customs' authorities, under the Trade Marks Act, for not bearing an imprint indicating the

place of printing. The Act, it appears, has had a material influence on the business of some foreign houses who have, hitherto, sent a large amount of work to this country. A considerable number of plates and blocks, used in illustrating English publications, have been made on the Continent, although they have borne no indication of the fact. The same remark applies to large numbers of collotypes which are supposed to have been of home production.

FINDING their English business being so much interfered with by the new law, more than one German firm, we are given to understand, have brought over their plant, appliances, and men to this country, and intend to work here. Hence the work, though executed in England, will, after all, be done by foreign workmen. Whether the competition, thus continued, will be keener than when the work was done abroad remains to be seen. Although labour may be cheaper on the Continent than it is here, it is somewhat doubtful if the foreign workmen, when they are here, will be content with less pay than their English *compères* receive.

THE question is often put as to which is the best reflector to use when enlarging by diffused daylight—a mirror of silvered glass or a white screen, such as opal glass or white paper? On this point opinions are somewhat at variance, even amongst practical men. As a matter of fact, however, the reflector, which is really the best, depends entirely upon the character of the light at the time of using. If the sky, for instance, be of a light blue, with plenty of white fleecy clouds about, then the silvered glass reflector will be the best. But if, on the other hand, the sky be of a deep blue, with an absence of white cloud—a “cloudless sky”—then a white reflector will afford the best means of illumination. In the latter case, the necessary exposure will be but a little more than half that which would be required if the mirror were employed.

AT a recent meeting of one of the photographic societies, the question was raised as to the best transparencies for enlarging from. Some advocated one process, and some another. Some of the best commercial enlargements, by the negative process, are from carbon transparencies, but in reality those by any other process, if equally as good, so far as vigour and gradation are concerned, will answer quite as well, and, under some circumstances, better. By reason of the varying thickness of the film itself in a carbon transparency, a species of halation is often seen, in the enlargement, where a deep shadow appears in juxtaposition with a high light. This, however, is not a very serious matter when the enlargement is made by diffused light. But when artificial light with a condenser is employed, the result is never so good as might be obtained from a transparency of corresponding quality, in which the image is of equal thickness throughout—say from a gelatino-chloride or a collodio-bromide plate.

IN England the carbon tissue supplied, specially for the production of transparencies, is made with a black pigment, but some supplied from the Continent is made with a reddish-brown one. Which yields the best results? The image of a carbon picture, whether on glass or paper, is built up of varying thicknesses of the pigmented gelatine, therefore it follows that the more actinic and transparent the colouring matter is, or the more it is attenuated, the greater thickness there will be in the opaque parts. Consequently, there may be a wider range of gradations secured than when the pigment is of an opaque character, and in a more concentrated form. Such transparencies however, although they might be better under some conditions, would not, by reason of the high relief existing, be so good for enlarging from by artificial light as those with a more level surface, like that obtained with an opaque pigment, or, better still, from a perfectly homogeneous film, like that of a dry plate.

ONCE more, this time on the authority of the London correspondent of a provincial paper, a photographer has been surprised when taking duplicate negatives of a young lady—who had just “died under peculiar and distressing circumstances”—to find that the subject had moved between the two exposures. Of course the doctor and nurse were

summoned, &c. We wonder how often this old and stale *canard* will be resuscitated, and from what source it will next make its appearance? This but a few months since we had it dished up in a very similar fashion.

THE *Illustrated Boston* has been prepared for interchanging with other organizations. It consists of a lecture, type-written, accompanied by sixty-six views for stereopticon entertainments; the text is also illustrated by contact prints from the negatives. Early in March a complete set will be shipped to Liverpool, and given to the Amateur Society of that city, in trust, for loaning to any amateur society of Great Britain that desires to examine or use it in giving an entertainment to its friends. This is, or will be, done, trusting that some of the Societies of the mother country will send to the United States similar illustrated descriptions of our localities.

ON applying to Mr. Steward—who is an agent for the Brin's Oxygen Company—for information as to the precautions taken by them to prevent accidents with steel cylinders, we are informed that the cylinders are made of soft steel, and of such a thickness in proportion to their diameter as to have a very large margin of safety when tested so as not to approach the elastic limit of the metal. Cylinders in which oxygen is compressed to 1800 pounds per square inch are all tested to 3000 pounds, both with air and water. Every cylinder brought into the works is tested, whether supplied by the Company or not, strange cylinders being frequently tested to destruction, and in no single case has any accident ever occurred, either at the testing or when the cylinders have been in circulation, from over-compression. Considerable precautions are taken to prevent the admixture of hydrogen with oxygen—all the hydrogen cylinders being painted red, and the oxygen painted black. Every cylinder brought into the works, whether it is a hydrogen or oxygen cylinder has the valve opened, so that the contents are liberated. Only the most experienced men are employed at the compressors, and separate pumps are kept for oxygen and for hydrogen.

FOURTEEN months only have elapsed since we gave an account of Suter's latest optical production in the form of a portrait aplanat, working with an aperture of $f=5.5$. We then stated, on the authority of Mr. Gutz, that M. Suter was indebted in no small degree for the large aperture he obtained to employing some of the recently introduced glass of Professor Abbe. Following still in the same lines, a still further improvement in this series, *D rapid aplanat*, has been made. Without in any way diminishing the angular aperture, and by a still further modification in the glass selected, the covering power, i.e., the ability to project a larger picture on a flatter field, has been considerably extended. Concerning that particular quality in the glass by which this has been effected, we do not stay to inquire, but it has also enabled the optician to extend the area of the dimensions; for whereas formerly the diameter of the glasses was confined to two inches, more or less, he has now introduced one of three inches, besides others more limited, all possessing similar characteristics as regards aperture and extension of field. We welcome the introduction or modification of any lens which will conduce to facilities in producing high-class work.

ECHOES.

I WAS much amused a few weeks ago at Mr. W. Brooks's indignation at having a formula for collodio-bromide emulsion fathered upon him by Mr. F. C. Beach, or Mr. Dunsterville, or some one; but I think he would have had still more right to complain of its “ragged” character if it had been stated in similar terms to two others which figure in a later portion of Mr. Beach's lengthy article. A fortnight ago I find a formula given on the authority of Mr. L. C. Landy, but due to Mr. H. S. Newton, and which was at one time considered of such value as to be kept secret. The peculiarity of this formula, to my mind at least, is that eighteen grains of silver nitrate are dissolved in ten drops of water and five drops of nitric acid. Twelve grains of cadmium bromide are separately dissolved in half an ounce of alcohol, and the two solutions mixed, after which the pyroxylene

and ether are added to complete the mixture. A second formula is mixed in the same manner, or at least it is directed that that order be observed. I need scarcely make any comment on the character of the emulsion likely to be produced in such a manner, considering that the silver haloids are directed to be formed in the entire absence of any colloid substance to promote fineness of division and ensure suspension and emulsification of the particles. But I do think that when a formidable paper is compiled from a variety of sources and read before an important society by one of its leading officers, it would be as well to devote just sufficient care to its details to ensure that any one ignorant entirely of the processes described may have some slight chance of success in attempting to follow the instructions given.

The old readers of the "British" of ten or more years ago will have little to learn from the republished formulae, and are not likely to be misled by any errors in the directions given; but the case is altogether different with the newer class of amateurs, who know collodio-bromide emulsion only by repute or in its prepared and complete form. To such the details of manufacture are quite unknown, and, being wishful of practising the process, a formula of such importance will recommend itself, and the instructions given by such an authority as Mr. Beach will be followed to the letter, but in this case, I am sorry to say, to the disgust of the experimenter and the discredit of collodion emulsion. The mistake is the less excusable because it is repeated in no ambiguous terms: "Add the silver solution and shake well, then add one ounce of ether," until which latter addition there is no collodion, and can be no emulsion.

I will merely add that if Mr. Beach's mode of working were possible, the compounding of a washed collodion emulsion, or of an emulsion of any sort, would be robbed of all its difficulties and troubles, for all that would be necessary would be to precipitate the bromide of silver rapidly, wash it, and then incorporate with the gelatine or collodion. But though "precipitation" processes have been devised, they have never come into general use.

I find another, at first sight, curious emulsion process in the list of published specifications of patents. The claim is for "a method for producing photographic emulsions not requiring a base or support," &c., and consists in the formation of a gelatine emulsion in the ordinary manner, but containing a larger proportion of gelatine than usual, and adding to it a certain proportion of potassium bichromate or other similar salt of chromium. This is spread upon glass or other smooth surface, properly levelled, and allowed to set, after which it is treated with sulphurous acid, then thoroughly washed in water, again dried, and finally stripped from its support in the form of a sensitive film.

I say at first sight the process seems a curious one in many respects. In the first place, an emulsion film of sufficient thickness to be "self-supporting," or capable of use without extraneous support, and containing the sensitive silver salt throughout its whole thickness, might appear a somewhat expensive one, but it is possible that the proportions of gelatine and silver may be so adjusted that the correct gradations are obtained in the negative, together with the necessary strength of film, without any undue expenditure of silver.

The use of bichromate of potash in gelatine emulsion is of course not unknown, but I have never hitherto, so far as I recollect, heard of such a film being coated previous to the removal of the chromium salt. Whatever other result may accrue, I can scarcely imagine a film of very exalted sensitiveness coming from such a combination, unless, indeed, it be finally treated with ammonia after the removal of the bichromate, in which case I should anticipate injury to the gelatine itself.

But the most noteworthy point in connexion with the patent is the resemblance to Froedman's method of making an insoluble gelatine support, more popularly known as the "Vergara film," a similarity, however, with an important difference. In Froedman's process the dried film of bichromatised gelatine is exposed to light previous to treatment with sulphurous acid, by which process it is rendered perfectly insoluble, the action of the sulphurous acid being then simply to decolourise the resulting tissue.

Exposure to light—at least for a sufficient length of time to thoroughly harden the gelatine—is of course practically impossible with a film containing silver bromide which has afterwards to be

exposed in the camera, though the presence of bichromate would suffice to protect it from slight exposure, such as would result in surface fog. This, in fact, is the function the bichromate has hitherto been called upon to perform in gelatine emulsion; but though it has been tried, I do not think that the preparation of emulsion in daylight has succeeded practically. Failing exposure to light, we have to seek other means for rendering the film insoluble, and these, whether effective or not I cannot say, are provided by the subsequent treatment.

Here, in fact, the sulphurous acid performs a totally different duty from that placed upon it in Froedman's process. The discolouration caused by exposure to light in the one case does not occur in the other, and the soluble bichromate would wash out of the gelatine film without recourse to any stronger measures than pure water; but by treating the chromated film with sulphurous acid the chromium salt is reduced, the sulphurous acid is oxidised to sulphuric, and the bichromate of potash is converted into double sulphate of potash and chromium or chrome alum. In fact, this is only a convenient if apparently circuitous method of adding chrome alum to the emulsion; convenient because it enables a large proportion to be introduced into the set film without in the slightest degree interfering with the fluidity of the emulsion or necessitating any special care in its management.

After treatment with sulphurous acid, we therefore have a film of gelatine acted upon by a more or less powerful dose of chrome alum, the effect of which, even after its thorough removal by washing, is to render the film insoluble when dry, and consequently, as may seem, similar to the Froedman or Vergara film. Such, however, is not the case, as the two tissues are very notably different in character, as any carbon printer will be aware.

Gelatine that has been subjected to treatment with chrome alum becomes, as is well known, insoluble after drying, but does not lose its power of swelling, more or less, under the action of moisture. Gelatine submitted to treatment with potassium bichromate retains not only its power of swelling, but also its complete solubility, *unless* exposed to light after drying, in which case, if sufficiently exposed, it loses both completely, and becomes as hard and impervious to moisture as so much leather or horn. Here, then, lies the difference between the two films.

The Vergara is, I believe, fairly easy to manipulate, owing to the absence of any tendency to curl or cockle, and requires no support or assistance in handling during development; but I should say that the new film would behave in a very different manner, swelling and curling, and generally "contorting" itself in a most objectionable manner the instant the developer touched it. I may be wrong, but my experience with gelatine films in the past does not lead me to hope for much from the new "supportless" sensitive films—I speak here from a mechanical point of view; from the photographic point, perhaps, the outlook is a little more promising.

The accident to Mr. Bowley has caused a not unnatural flutter in the breasts of photographers who are users of compressed gas, which it is claimed removes nearly, if not all, the danger attending the use of the limelight, even in careless hands. Sad as the result has been, and bitter the lesson, it is at least some consolation to know that the accident, if so it can really be called, was the result, so far as present evidence would seem to show, of an almost culpable carelessness—not negligence, but wilful carelessness bred almost of contempt for the danger courted. That the fatality was so limited, as it proved, was perhaps the greatest "accident" of all, for it is terrible to think what might have happened at any period during the travels of the cylinder of mixed gases. Let us hope the lesson will be taken to heart. One point is disposed of, *viz.*, the belief or assertion that in bursting the iron bottles would "rip" rather than fly in fragments; the facts of the recent occurrence point quite in the contrary direction.

What very contradictory information "Aliquis" has obtained in reply to his query on the subject of Photographing in Norway! What he wanted to know specially was whether he could rely upon having plates sent after him (or before him) from place to place, without having the trouble of dragging them with him. The Rev. A. M. Macdonald, speaking from the practical experience of four seasons' actual work in Norway, gives an altogether satisfactory reply, while another correspondent regales him with a story, which he evidently considers

ben trovato si non e zero, and which is quite the reverse of Mr. Macdonald's experience. However, experience is experience, while a story, whether true or not, is misapplied if it is to mislead.

Mr. H. M. Smith wants to have a "dealers' section" at the Convention, but why confine the principle? It may not be possible yet, but I do not see any reason why there should not be not only a dealers' section, but a section for amateurs, for professionals, for art, for chemistry, manufacturers, &c. &c. On the principle of the British Association, with its various sections, I fancy more useful work would be got through in the limited time the Convention lasts, and the members of "all sections" could meet together at the excursions and *conversaciones*, as do the "Britishers."

JUNUS.

THE PROPERTIES OF DETECTIVE CAMERAS.

No. I.

"In the multitude of counsellors there is safety." This axiom, doubtless, was running in the head of Mr. H. T. Duffield, of New York, when he decided that in order to present an average summary of the qualities and properties required in a detective camera, he placed himself in communication with several users of that now popular instrument. The experiences having been gathered in, Mr. Duffield has presented them *in extenso* to the local Society, together with a brief summing up of their properties by himself. This we shall here present in a condensed manner.

In reply to the question:—

1. What sort of detective camera do you prefer?

In this Council it appears that the quarter-plate was the size preferred by the majority; 5 x 4 taking second rank.

2. Is it necessary that the camera be so constructed that observers' attention will not be called to it?

The majority answer "No;" but it should by preference be made unobtrusive; it is almost impossible to so construct it that people will not "catch on to it;" but that nothing, however, that tends to affect the simplicity of the mechanism of the camera should be sacrificed in making it inconspicuous. A number think the detective cameras of to-day sufficiently unobtrusive for all ordinary purposes, especially street work.

3. Which is the best way to hold the camera while making an exposure so that it will be steady?

The preponderance of opinions is in favour of it being under one of the arms, the right generally, pressed closely to the side, the hand of that arm keeping it steady, while the other hand operates the release of the shutter.

(a) "I rest my larger boxes on my left fore-arm, not touching the body; the right hand works a bulb, and does not touch the body."

(b) "I have a push button on the right hand side, upper corner front, of my camera; I take a firm hold with the left hand, palm on the bottom, and steady with the thumb on the side, and then with nearly the same position of the right hand on the right side of the camera, and thumb pressing on the push button, or handy to it. I take a firm hold with the right, and I never have a blurred negative. At one time I pressed it against my side and found at times blurred negatives."

(c) "Under the right arm, with the right hand reaching under the box and one or two fingers controlling exposure by pressing a button at will. If the camera be so held, any motion communicated to it by the body will be a slow one, and for ordinary exposure there will be no movement noticeable. I never had any case of shaking in the detective camera."

(d) "Under the arm, resting upon the hip. Hold your breath when pulling the trigger. Do not rest the camera upon the stomach, and bend over it as though you had an ache in that locality; it is not graceful, and always attracts attention."

4. Should not the camera have a springback?

For detective work, it is not necessary; for view work, quite essential, is the general opinion.

(a) "No; because this requires a small stop, and thus prevents instantaneous work."

(b) "Would prefer a rising front."

(c) "Decidedly yes; and I see no reason why manufacturers have overlooked this very important feature."

(d) "Yes; two of them."

(e) "Certainly, if architectural effects are to be reproduced; for landscapes, not necessary."

(f) "If it would work automatically."

(g) "It is best to keep the detective as simple as possible."

5. Do you think it necessary to have a finder? Should there not be two? Should there not be hoods over the finders?

Four consider it needless; seven, that it is an advantage to have a finder, but not absolutely necessary; twenty-eight, that it is indispensable; nine, that one is sufficient; twenty-nine, that two are desirable. Hoods are also considered desirable.

(a) "I have two finders on my camera; a camera without any would be of

no value to me; when you want to take a picture either way (vertical or horizontal) you must have a finder for each position to be sure of your field."

(b) "A finder is quite needless; if three round head screws be placed on the outside of the camera to indicate the angle of view included on the plate, this will answer all purposes."

(c) "A finder is very necessary; one is sufficient, as it can be viewed as easily from the side as above; a cover, hinged and standing upright, serves as a hood."

(d) "I think one finder is absolutely necessary, but do not see the advantage of two; but I do think it should have a hood, as at times I find it almost impossible to get along without one, and, in fact, have concluded to put one on my box on a hinge; for, outside of its usefulness, it is a means of hiding the purposes of the box, and makes it a little more mysterious, or rather less conspicuous, to the uninitiated. I make a hood with my hands to answer the purpose until I get the chance to make a good one on hinges."

(e) "I think two finders so essential that I shall have an extra one put in; the hood I do not feel so necessary, as I make a hood of my hand."

(f) "Have tried without and with finder, and emphatically pronounce in favour of finder; do not consider a hood necessary; good only to keep off dust."

(g) "Finders essential, and to embrace the same angle of view as the lens cuts on the plate; certainly two; hood to screen off the light an improvement."

(h) "Very important to have two finders; if well sunken in the box there is no need of hoods."

(i) "Only use one finder, as the other cannot be made exact; consider hoods necessary."

(j) "Two finders necessary, and also sights."

(k) "Not essential; the large finder or full plate on which to focus I consider a powerful aid to intelligent composition and the study of nature."

6. Should not the detective be made solely for detective work, and not also be arranged for view work?

Nine answer for detective work only, twenty-nine for both.

(a) "I believe that it should be arranged for detective work only."

(b) "If 'detective' be used, in the strict sense of the term, it should not be so arranged; otherwise, yes."

(c) "If only for detective work, many of its appliances may be abandoned; while if used for view work also, too many cannot be added."

(d) "For detective, not tripod use, but should have a time shutter."

(e) "For the average amateur both ways."

(f) "Immaterial, provided the arrangements for time pictures are not complicated."

(g) "There is no need of a tripod attachment to the camera; all that it is capable of doing can be accomplished holding it in the hands."

(h) "The vest camera and others of that class are the only true detective cameras; the province of the so-called detective I consider to be the production of satisfactory pictures of moving objects or random bits of interest to tourist or pleasure seeker, or notes for the artist, architect, or engineer, to be gathered right and left with minimum of effort."

(i) "If the camera is as large as 4 x 5, it adds to its value to have it arranged for view work; I have used mine with a tripod for time pictures, and have made my best work with that arrangement."

(j) "I should not have bought a detective unless it might be used for view work."

7. What should be the focal length of a lens to cover with full opening the plate used?

(a) "The lens should be of about six inches equivalent focus, and should cover the plate all over with a stop of f.11."

(b) "I prepare a size larger lens than the plate used for various reasons, both for covering power and focal length."

(c) "The lens should be one size larger than the plate, i.e., a 4 x 5 for a quarter plate, &c."

(d) "Focal length should equal or exceed the diagonal of plate, and aperture should be as large as possible, f.4, if it can be obtained with good covering power and definition."

(e) "Not larger than seven-inch focus for a 4 x 5 plate, that gives an angle of 39°; six-inch focus would be better, covering a view of 45°."

8. Do you prefer a rapid rectilinear or a wide-angle lens?

Thirty-five, rapid rectilinear; two, wide angle; one, both.

(a) "For confined situations, of course, the wide-angle is best; but, for general work, give me the rapid rectilinear."

(b) "The lens for detective work is yet to be made, of an angle of view between 30 and 40°."

(c) "The rapid rectilinear at f.8 is a necessity, but f.6 is better; and these apertures cannot be obtained in a wide-angle lens."

(d) "A medium wide-angle is best."

(e) "It should be a moderate angle, so as not to greatly distort the perspective."

9. Is it not an advantage to have both of these lenses, and should not all detectives be so constructed that the lens can be quickly changed?

Twenty, no; fifteen, yes.

(a) "I do not think it would be an advantage to change from a rectilinear to a wide-angle lens, unless the necessary change of focal length could be effected automatically at the same time; to change one and not the other in a hurry would cause disheartening failures."

(b) "This would involve too much complication, and would perplex the artist, and lead him into errors and regrets; too much choice is injurious."

(c) "I think it would be an advantage."

(d) "Do not see the necessity; would make construction of the camera

proper more complicated, unless lenses of the same approximate focus were used; all lenses for any kind of work should have bayonet joints and fit in the same flange, within limits of course."

(f) "(a) Yes; (b) It would be a convenient arrangement."

(g) "The use of two lenses in a detective camera is not advisable; it is sure to confuse the operator, particularly in focussing."

10. *How does the single lens do for this kind of work? Is it rapid enough?*

The majority answer that they have never tried the single lens for detective work, and therefore cannot express any opinion."

(a) "No, except some high grade lenses."

(b) "A good single lens works quicker and with deeper range of definition than a doublet of the same aperture."

(c) "Of two lenses of equal focal and openings—one single and one double combination—the single should be the quickest if made of the same glass."

(d) "Yes, with good light, but it is apt to distort somewhat."

(e) "It will do well where there is brilliant illumination; I have taken instantaneous pictures with it at the sea-shore."

(f) "Single lens will answer for some kinds of work in summer."

11. *Do you use a fixed or moveable focus?*

Ten, fixed; twenty-eight, moveable.

(a) "I use a fixed focus with all my cameras; the $4\frac{1}{2} \times 5\frac{1}{2}$ works sharp for 40 feet and beyond; the $3\frac{1}{2} \times 4\frac{1}{2}$ for 25 feet and beyond; the others still shorter range."

(b) "Fixed focus at 18 feet."

(c) "Both."

(d) "Focus for every view, estimating distances, 8, 10, 12, 15, 20, 30, 50 feet, and distance."

(e) "Moveable focus I think is indispensable."

(f) "Moveable, but seldom used except for very near work."

(g) "Moveable from 10 feet to universal focus about 100 feet."

(h) "A moveable focus with seven-inch lens on 4×5 ; but if I used a shorter focus lens I should use a fixed focus."

12. *What diaphragm do you chiefly use in summer and in winter, the summer season being from May to November, and the winter from November to May?*

General answer: In summer, $f-15$; in winter, $f-8$ to full opening.

(a) "Always $f-15$, only changing the speed of the shutter."

(b) "For street work the next stop to full opening, and for water the next smaller in summer; for street work full aperture, and for water the next stop in winter."

(c) "The largest, varying exposure by the speed of the shutter."

(d) " $f-11$ always."

(e) "Third, whenever I can."

(f) "Full opening."

(g) "About $f-8$."

(h) "Depends entirely on conditions; no one more than another."

(i) "Summer, medium or next largest; winter, the largest; I never use full opening."

13. *Which diaphragm is best to use when the object is in bright light and in shade?*

General answer: Bright light—summer, $f-16$ and $f-22$; in winter, $f-8$ and $f-11$. Shade—summer, $f-11$ and $f-16$; in winter, $f-8$ and $f-4$.

(a) "Of course the diaphragm varies very much with the conditions of light, but the object of both of these questions was to ascertain the stops generally used. For marine views, $f-22$."

(b) "I always use the largest diaphragm I can; don't think I ever estimated a plate very much."

(c) "I generally use the largest diaphragm that I consider will do the work."

(d) "At the sea shore, $f-22$; when snow is on the ground, $f-16$ and $f-22$."

(e) " $f-16$ in bright light, summer, otherwise $f-11$; I prefer to use as rapid a shutter as possible."

(f) "I vary my diaphragm very seldom."

14. *What is the principal fault of your shutter?*

Fourteen are satisfied with their shutters.

(a) "No definite means of regulating its speed."

(b) "No means of knowing its speed."

(c) "No means of adjusting speed."

(d) "Arranged simply for instantaneous exposure."

(e) "To control the speed more perfectly, or at least to know its speed."

(f) "That it gives uniform exposure of the whole field."

(g) "That the speed of exposure is not uniform, being more rapid at the beginning."

(h) "That you can never be sure of the speed twice running the same."

(i) "Cannot change the speed as quickly as I would like."

(j) "Not quick enough."

15. *What is the average speed of your shutter when making exposures?*

(a) "Winter and summer, 1-20th of a second."

(b) "Generally give it slowest speed, except for marines, ice, snow, &c."

(c) "From 1-10th to 1-100th of a second (!); in summer, 1-10th to 1-100th; in winter, 1-10th to 1-20th."

(d) "Summer, about 1-40th of a second; in winter, 1-20th."

(e) "As fast as it will go, say 1-10th of a second."

(f) "As fast as it will go."

(g) "Highest tension of speed."

(h) "Highest speed, 1-200th of a second; lowest, 1-80th."

(i) "Probably 1-20th of a second."

(j) "Prefer slow shutter."

(k) "Half speed generally."

(l) "About 1-50th of a second in summer; about 1-20th of a second in winter."

(m) "Except on the water, as slow as possible."

(n) "Summer, 1-50th to about 1-100th of a second; winter, as slow as it is possible to get; subject still and sharp."

(o) "Summer, 1-40th of a second; winter, 1-25th of a second."

The majority of the answers reply: "Don't know," and "Can't find out." The beautiful candour of this general reply, when there was such excellent opportunity to display scientific knowledge, shows that the character of the photographer is susceptible of the highest moral cultivation.

16. *Should there not be some means of indicating the speed of the shutter?*

Thirty answer, "By all means;" eight, "Not necessary."

(a) "No, as any one with experience can guess."

(b) "At least some means of getting the same speed as often as wanted."

(c) "Yes; that is the fault which most detective cameras have; mine has a lever which can be moved forward and back one inch, and I can accurately judge the speed of my shutter."

(d) "Yes, I could record mine by number only, which would be useless for comparison."

(e) "Do not think it necessary; your judgment and experience should tell you what speed to use, and it takes quite a long experience to do artistic shutter work."

(f) "Yes, if reliable; but I doubt if a trustworthy indicator would show the degrees of speed above 1-100th of a second."

(g) "Don't think it would be any great advantage; detective cameras are already too complicated."

(h) "Good photographs can be and are made without this means, but I think much better and more uniform results could be obtained with it."

(i) "Yes; though I always use my shutter at full speed, and depend on development to correct any error, except in case of shade, when I slow my shutter."

(j) "A spring that is in tension constantly becomes fatigued and fails to give the same speed as at first; this is especially true of phosphor bronze; exposure at various speeds of the shutter on falling bodies, and measuring and calculating, gives the most correct results of the time of exposure and a ready means of checking off results at any time; the speed of shutter and diaphragm of lens used depends on sensitiveness of plate employed, season, time of day, and rapidity of motion of subject, and must be modified accordingly."

(k) "Yes, there should; I consider it a much-needed improvement."

(l) "Not without one had some effective light gauge."

(m) "Desirable as a matter of curiosity."

In the foregoing answers, so skillfully extracted from so many users of "detectives" by the ingenious Mr. Duffield, attention has been confined to the mechanical side of the question. In our next we shall present in a similar "boiled down" manner the views of the councillors relative to the treatment of the plate after exposure.

EXPERIMENTS ON THE REPEATED USE OF THE DEVELOPER.

A SERIES of experiments, into which I was led by circumstances not directly connected with the subject, may prove suggestive to many of those who favour the practice of using the same developing solution—pyro, hydroquinone, or ferrous oxalate—for a number of successive plates. The feasibility of such a course has never been doubted, though in the case of pyro, for fairly obvious reasons, it has not come into use; but with ferrous oxalate, and more especially with hydroquinone, this power has been seriously put forward as an advantage in those forms of development.

That the active principle of the developing solution is not exhausted in a single operation scarcely requires argument, and so far as the mere act of development or the production of a visible image is concerned all developers are capable of repeated use, but for practical purposes the question, of course, is whether the results produced are satisfactory. For my own part, I have always held the negative opinion, chiefly on the ground of uniformity of action, for it must always be borne in mind that, however large a surplus of developing power is carried over to successive developments, there is also a constantly increasing restraining influence derived from the films already developed. Every plate developed introduces a certain quantity of bromine into the solution, and this added restrainer, coupled with the natural exhaustion of the developer from use, must seriously modify its character every time it is used, and though the trouble may be minimised by employing a considerable volume of solution—which of course destroys the economy of repeated use of the same solution—the want of uniformity is never wholly done away with.

The experiments to which I refer were made with collodion emul-

den films which are well known to be greatly more susceptible to the restraining influences of bromide than films of gelatine; but though the immediate results may be more marked, the principle remains the same, and similar effects, though probably in a diminished degree, are to be anticipated with gelatine plates.

I was led into these trials in the following manner:—Having a large number of lantern plates to develop, I thought, for economy's sake, to utilize the power of repeated development, so made up a quantity of solution from which to work. For the size of plate mentioned I employ two drachms of solution, using it from a small tipped measure, and in this instance I made up four ounces of solution, intending after each development to pour the used solution back into the stock bottle and mix with the bulk. The solution contained hydroquinone, one grain; sulphite of soda, four grains; one hundred-grain solution of carbonate of potash, thirty minims to each ounce.

The first plate came up satisfactorily, though very slowly, which I put down to the temperature, the weather being frosty and the thermometer out-of-doors standing some degrees below freezing. The second plate was slower, the third still slower, showing no trace of image in ten minutes after the first application of the developer, though the exposure had been practically the same throughout. By the addition of more alkali I managed to get the picture out, but the final result was far from satisfactory, owing to the quantity of potash solution used being more than the film would stand. A fourth plate, without the addition of more alkali, at the end of half an hour showed only the heavy shadows, but these very dense, with very little prospect of getting out the details.

I could scarcely conceive that the result arose from either low temperature or from the minute quantity of bromide introduced into the large bulk of solution by the act of development, but I resolved to try it either, and which, cause was to blame. One ounce of fresh solution of the same composition was made, and, selecting a rather thin collodion negative with perfectly clean shadows, a test exposure of twenty seconds was given at a distance of twelve inches from a No. 6 Iray's burner, and this was developed with my standard solution of three grains of pyro and one minim of strong ammonia to the ounce. In the result the exposure proved to have been too much; fifteen seconds, or perhaps less, would have done.

With the same negative an exposure of fifteen seconds was next given, and the hydroquinone developer applied; the picture came up slowly as before, about two minutes elapsing before any image appeared, and development was complete in a little under eight minutes, the result being perfectly satisfactory. The slowness in the appearance of the image could be accounted for by the low temperature and the use of sulphite with the hydroquinone. The used developer was returned to the stock bottle, and a second plate was exposed under precisely the same conditions. Upon developing this, the time required for the first appearance of an image was found to have increased to nearly five minutes, and after a continued application of the solution for a quarter of an hour, a picture was obtained of great vigour in the shadows, but scarcely showing sufficient detail in the lights. In fact, it was a result which, compared with the previous one, was undoubtedly to be described as under exposed. A third plate, exposed under similar conditions, was still slower in development, and exhibited stronger symptoms of under exposure.

In order to ascertain if the temperature was the element at work in producing this result, a supply of hot water being at hand, the developing solution was raised to what we are accustomed to consider the normal temperature, namely 60°, and another plate exposed under similar conditions to the previous ones. In this case the development proceeded more rapidly, the image appearing in about a minute, and for some time going on with the usual speed; but a point was reached at which it apparently came almost to a standstill, and the continuation of the action up to a quarter of an hour failed to produce the full amount of detail, though as regards vigour and "punch" the result was remarkable.

Several more exposures were made, the temperature being kept as nearly as possible at 60°, and the times were increased gradually up to thirty, and, finally, forty seconds, but each successive development became slower and more prolonged, and each succeeding image denser and more remarkable for the contrasts it presented. Even with forty seconds' exposure and an application of the developer for twenty minutes the high lights of the positive were wanting in detail, and the general character of the result was that of a hard under-exposed picture.

Departing now suddenly from the use of the "stock" developer I had been employing, I mixed up a fresh batch of the same strength, and at a temperature of 60°, as before. Another plate was exposed for thirty seconds, with the result that it was hopelessly over exposed, the image "rushing" out in about fifteen seconds, and veiling over

completely in a very short time. I then returned to the fifteen-second exposure, and employing a fresh quantity of previously unused developer got a perfectly exposed picture, the image commencing to appear in about twenty seconds, and proceeding regularly until the development was completed in a trifle over four minutes. The character of the image was in every way different from those that had gone before, being quite devoid of the hardness and "rawness" in the lights of which I have spoken, and exhibiting none of the extraordinary density produced by the previously used developer.

Going back again to the cold developer originally employed, temperature 34°, the only difference I could detect was in the time occupied in development, the character of the final image differing in no respect from that produced with the same exposure and the higher temperature solution. With thirty seconds' exposure the picture was as badly over exposed at the finish as when the warmer developer was employed, though the action proceeded very slowly, and for a time seemed likely to give a good result. But at a point where the last details were still incomplete the plate suddenly veiled, and lapsed into that appearance of heaviness and want of sparkle that so strongly marks an over-exposed transparency.

The result of these experiments is to my mind conclusively against the repeated use of the same developing solution. I admit that possibly—nay, probably—the effects would not be so pronounced in the case of gelatine plates, nor, perhaps, with either pyrogallol or ferrous oxalate, but I am convinced that in a small way of working, or for amateur purposes, the practice is not to be recommended. The economy is, after all, but a small one, while the counterbalancing element of uncertainty far more than annuls any benefit that might accrue from that source.

I do not for a moment condemn the employment of ferrous oxalate for successive developments of gelatino-bromide paper, where, especially in the case of large sizes, the economy is considerable. In the first place, the effect produced by the increment of restrainer is much less powerful than in the case of hydroquinone, the additional sparkle given is an advantage rather than otherwise, and the extra time occupied in development is not very material. But where ferrous oxalate is thus employed, I think it is of importance that a liberal quantity of the solution be used in order that the change in its character may be as slight and as gradual as possible.

W. B. BOLTON.

DANGER OF MIXED GASES.

"It is an open secret in Dublin that the victim lost his life through trying to succeed in mixing the gases in one cylinder under pressure in such proportions as to burn at the orifice instead of exploding, and, unfortunately, in the end, caused an explosion within the cylinder, blowing it to pieces. Even then he would have escaped with the loss of his left hand and one rib fractured, had not one small piece of the cylinder struck him just under the left ear, tearing the carotid artery and fracturing the base of the skull in its passage. It was a great pity, for a better fellow never breathed; he was everybody's friend."

These are the exact words of a correspondent on the spot to the writer.

The writer in his youth studied chemistry and the other natural sciences at University College School, and these being just to his own heart soon became the assistant demonstrator to the Professor who took these classes. One of the experiments was the burning of the mixed gases, hydrogen and oxygen, in the proportion to form water, from a bladder. The jet used was what was then known as a Hemmings's jet, which consisted of a tube of about nine inches in length and three quarters of an inch of internal diameter, tightly packed with very fine copper or brass wires, in the middle of which a pointed brass rod was forcibly driven, thus only leaving a series of infinitely small tubular interstices for the gases to pass; a stopcock at the end of a solid brass nipple, with a very fine drill hole—of course with a platinum tip—completed the jet.

The flame was almost invisible in daylight, of a pale blue colour, and barely a quarter of an inch long, but melted platinum wire instantly. With this jet, used repeatedly by the writer, no accident ever happened. After he left school he still continued his studies, and was fortunate enough to have a workshop of two floors, with windows the whole length, the upper of which he fitted up as a chemical laboratory and the lower one as a workshop, with lathe, &c. This was in 1862. Being fairly provided with pocket money for the purpose, one of the first things to undertake was to provide himself with a similar Hemmings's jet. Being of a mechanical turn of mind also he made the greater part of it himself, including the packing of the wires, and an indiarubber bag of about one and a half cubic

feet capacity. This apparatus was only used once, for the bag exploded under his arm, without, however, doing any more harm than breaking about a dozen panes of glass. He also was in the habit of trying the well-known experiment of filling a soda-water bottle with the mixed gases, and firing it, with, of course, a towel wrapped round it, but at last the bottle burst in his hand into a thousand fragments, without causing the slightest abrasion, and he then abandoned mixed gases for ever.

He therefore considers himself justified in forming the conviction that mixed gases cannot be burnt safely, no matter what precautions are taken, and that, therefore, the ethox burner is wickedly dangerous, and ought to be prohibited by law, as also the benzoline substitute.

Explosions with bags never happen from what is euphoniously but wrongly described as back pressure. What always happens, whether to amateur or professional, is that the bags are not distinctly marked "H" and "O." The hydrogen pure (or carburetted) always burns in greater proportion than the oxygen. There is, therefore, always an excess of oxygen left. The oxygen bag is filled up with hydrogen.

This is what happens with professionals. They always talk of the oxygen as *gas*. They are extra busy, and Bill, a novice to the trade, is taken on as help. "Here, Bill, fill this bag up with *gas*." Bill takes the bag to the gas main and fills it up; the operator starts the performance, and can't get a good light. Tableau!

In coal mines, too, the initial cause of explosions is an outburst of compressed carburetted hydrogen—frequently released by a low barometer—meeting with a light, but it is instantly passed on to part of the workings which, although then quite free from gas, by repeated explosions is now charged with the very fine particles of coal with which the air of the mine is always impregnated. GEORGE SMITH.

MAKING UP FORMULÆ.

There are many things in photography that are suffering from lack of uniformity. Lens flanges are never made with the same threads for the same size lenses of different makers. American, English, and other European dry plates are all made of sizes to suit the whims of some particular set of individuals without any regard to the tourist who has a camera made in one section of the globe and finds himself in need of plates in another. If the makers of other pieces of mechanism were as thoughtless about the wants of their customers as the makers of photographic cameras, lenses, and plates, the advances in modern engineering would never have been made. But we think that the greater part of this confusion in things photographic is principally due to the photographers themselves, both the professional and amateur. For what is more bewildering than the hosts of formulae one sees in the photographic journals of to-day, the utterly reckless manner of naming the chemicals for use in them, and the confusion one gets into in trying to make up solutions for developers, baths, &c.

One writer will tell you to use hydroquinone; another, hydrochinone; and a third, hydrokinone. With, perhaps, a limited knowledge of chemistry you go to the photographic merchant and ask for hydroquinone. A polite and well-meaning salesman hands you a bottle marked hydrochinone or hydrokinone, and assures you it is the material you mean. This is perfectly true; but you have your doubts about it, carry home your purchase, develop a plate with it, and—fail. Now the first thing you do is to blame the salesman, believing he has given you the wrong material, when the real trouble is with yourself, and the wretched doubt produced in your mind by that label which does not correspond to the name given in the formula you wish to use. As a matter of fact, hydroquinone is the English equivalent of the German words hydrochinone or hydrokinone. These latter should never be used in English, and the manufacturers should be more careful about the labels they put upon the bottles.

Again, the writer of a formula tells you to use sulphite of soda. You again proceed to buy the material for use, and the first question you are asked is: Crystals or granulated? Thinking you have not carefully read the formula you hesitate to make the purchase, and return home to find yourself still in doubt, because the author of the formula fails to tell you which he means. The fact of the matter is, that the granulated sulphite is very much stronger in true sulphite of soda than the crystals; and very often formulae are given in which, if you use the granulated salt, you would find it impossible to dissolve the quantities specified. As a matter of fact, the crystallised salt contains fifty per cent. of water, while the granulated salt contains none. The same argument is true of carbonate of soda. In this latter salt we have about sixty-three per cent. of water in the crystals, while the granulated variety contains about fourteen per cent.

In the case of potassium carbonate, we have no such difficulties as those mentioned above as occurring in the case of sodium sulphite and carbonate. The potassium carbonate usually occurs in commerce as a powder, free from water. Occasionally a crystalline variety is seen that contains about eleven per cent. of water; but this salt is not often found for sale.

The true and only way out of this confusion is to use the hydrometer for making up solutions for developers. This has already been adopted by some of our dry-plate makers in the printed formulæ given in their plate boxes. If you tell a man to take a given number of parts of a solution of a given degree of density on a Beaumé's hydrometer, he is much more likely to get it right than if you tell him to take so many ounces of a salt without specifying the condition of the salt.

Indeed, it has for a long time been a wonder to us that photographers will use a hydrometer to test their silver baths with, and entirely ignore its use in every other solution that they make up. Such an instrument should be their daily companion, and we are certain that it will cause less trouble and give more uniform working in the dark room than any other method that we know. For example, a saturated solution of carbonate of soda stands at 19° Beaumé, and contains about thirty-nine per cent. of the crystals. A saturated solution of hyposulphite of soda stands at 40° Beaumé, and contains about sixty-three per cent. of the crystals. These degrees of density on the Beaumé hydrometer are for the ordinary temperatures, 60° to 70° Fahr.

If the writers of formulae would only state how much of a solution of sodium carbonate or sulphite, of a given density, is to be used, the question of the use of the crystals or granulated salt would never come up, as the density of the solution depends upon that true salt present without regard to the amount of water it contains. Thus, to make a developer, it might be said:—

Take—	
Sodium carbonate 10° B.	1 part.
Sodium sulphite, 10° B.	1 "
Water	4 parts.
Pyrogallol	10 per cent.

By this method the developer could be made up by adding two solutions of definite strength together, and any given quantity of pyrogallol could be added according to the volume of the mixture made up. Furthermore, any desired dilution of the developer could be very accurately stated by mentioning the degree Beaumé which the weaker solution should mark. Saturated solutions of any of the ordinary salts are not to be recommended; but any weaker solution, provided its density is known, could readily be used, and is far more easily made.

We hope we have said enough to induce the writers of formulae to state in more definite terms just what they mean. And if we could all agree upon the use of the hydrometer, a much better understanding and far less trouble and failure with dry plates would be assured. We are compelled to believe that much of the trouble between the makers and users of dry plates would be overcome if solutions of definite strengths were recommended, and not a number of salts dissolved in one solution. If the salts are separated, the quantities of each could be much better regulated to suit different circumstances—changes of light, character of view, time of exposure, and many others. Under the present régime very little margin is given in most of the formulae, and in a great many all that can be done is to add more or less water.

Can we hope for more definite statements of formulae? With the increasing intelligence in the ranks of photographers we believe we can. —Anthony's Photographic Bulletin.

HYDROQUINONE.

[A Communication by Mr. T. Charters White, on Thursday, January 3. Sir George R. Prescott in the chair.]

THE wise man admonished his readers that "of making many books there is no end, and much study is a weariness to the flesh." Had he lived in these days, and devoted his attention to photography, I think he would have justly said that in the multiplication of developing formulae there is no end, and the study of their action is a weariness and a distraction to the mind of the immature amateur; for it is as if he would go from one end of this big city to the other, but instead of being taught to go by its main arteries, he were to be guided by every stray wayfarer he asked, and should be directed by them to take their favourite way, and to follow his path through devious by-roads, till he became lost in a labyrinthine maze, and ended in confusion. So every practitioner of what has, by reason of its dirty stains, been called the black art, has his pet formula, and because he can, by reason of its subtle combinations and its fractional measurements, produce a well-developed negative, he straightway, in the fulness of his heart, imparts it to another worker, who, not possessing his friend's acumen, becomes landed in a hopeless mess, tries his formula on somebody's new brand of plate, modifies the formula after some fashion of his own, and gets a worse result than ever. It has often seemed strange to me that, considering bromide of silver forms the principal element in the formation of a sensitive gelatine emulsion, something like a universal developer could not be devised; but till that event is consummated, I suppose the amateur must go on floundering amidst the waves of this ocean of formulae—that is, if he is not contented to produce a negative which will give a good print, and be simply the means to the end he has in view. My impression is that this much-to-be-desired developer is to be found in hydroquinone. Prior to the year 1880, hydroquinone was regarded more in the light of a chemical curiosity than of any practical utility, till Captain Abney, in that year, suggested its

use as a photographic developer, whilst its high price at that time precluded its employment to any great extent. While closely allied to its kindred pyrocatechin and resorcin, both of which substances have been recommended as developers by Dr. Eden, it yet differs slightly in its chemical formula, containing one atom less of oxygen than the other two. Hydroquinone, according to its historians, may be readily obtained by distilling one part of quinic acid, four parts of manganese dioxide, with one part of sulphuric acid, the latter being diluted with half its weight of water. A gentle heat being applied, dense white vapours pass over into the receiver and condense into shining spangles of quinone. By the subsequent employment of suitable hydrogenising agents, the quinone is converted into hydroquinone.

Although this is, roughly speaking, one method of its preparation, it is now largely obtained from a combination of aniline, sulphuric acid, and bichromate of potassium, by which its cost is lessened, and which an increased demand may still do much to lower, as in the analogous instance of pyrogallie acid. So much for a very brief sketch of as much of its chemistry and photographic birth as I have been enabled to gather from the photographic publications. We must now consider, as conclusively as the time allotted to this paper will permit, what is of more importance to us as practical workers than its chemical history, namely, the advantages to be derived from its use as a developing agent.

The photographic literature of its early days teems with complaints of its slowness as a developer, and hence its general use in this direction was attended by so much disappointment that its use was discouraged; but as its management became better known it has come to the front again, and will have a fair trial, as it undoubtedly possesses many advantages over other developers with their complicated and intricate formulæ.

These advantages we will now consider.

I do not pretend that my observations should be taken as based upon exhaustive or systematic experiments. I have neither the time nor the ability to devote to this research; but my experience of its advantages to the amateur are such as to lead me to recommend its more extended use, with the view of modifying it to suit various classes of work and adapting it for varying exposures, and if it can be made suitable for landscape work, and for instantaneous as well as time exposures, then we shall have a developer which will enable us to diminish our stock of bottles in the dark room to two—one for the mixed alkalis, the other for the hydroquinone. As the latter does not require any restrainer we do not need any bottle of bromide solution, and as it can be used for the development of the various makes of bromide papers no ferrous oxalate solutions are required; therefore, two more bottles are dispensed with. As with this developer any amount of density can be attained, we want no intensifying solutions, so here go two more bottles; but this diminution in the number of bottles does not by any means exhaust the list of its advantages, one of its most marked being the entire absence of fog, with the mixed alkali, unless in the presence of ammonia, when a veiling may take place depending in degree upon the quantity employed, producing in some instances almost the appearance of a colloidal-bromide emulsion. Its great advantage to me in photo-micrography is its capability of rendering fine detail without that blocking up which arises from lateral development by which delicate lines become almost closed up, and which I have frequently found from the use of pyro; it appears to my mind an excellent developer from this peculiarity for those who have the photographic copying of maps, plans, or line work of any kind. Of course this absence of blocking up may be more apparent than real from the absence of fog, which may make the fine detail appear clearer and sharper than does pyro, but it is a point which will be all the better if investigators will examine and verify. We may reckon amongst its advantages that of its cleanliness, as evinced in the freedom from stains on either negative, hands, or towels, although the latter become brown, but as they are saturated with alkali they are easily washed. Some objections have been raised on the score of its being rather more expensive than pyro, but I think these are unreasonable and untenable, as one bath of developer may be used for at least four negatives without losing its power to any great degree. One foreign worker with it was accustomed to make up a large vertical grooved bath of it, and leave all his negatives in till they were fully developed, but while I cannot recommend such haphazard work, it will serve to show its power and its economy as a developer against pyro. If that is not enough, the old mixed developer, instead of being thrown away, may be bottled off for future use, and after a fortnight it has been found retaining a considerable amount of energy.

One other advantage arising out of the use of hydroquinone is the ability to take a mixed developer in travelling abroad, to be enabled to test exposures, and without the mess and the staining of bedroom utensils arising from the use of iron or pyro.

And yet another advantage which may be considered in conjunction with the last, and that is the amount of light which may be employed in comparison with that to which we are restricted in the use of pyro. In one case a gentleman, whose name I now cannot remember, once developed a plate in the open room, merely adopting the precaution of standing with his back to the gas while using this developer. Now this ability to stand more light is an advantage to those whose eyes are likely to be strained and damaged by the semi-obscure light hitherto necessary with the usually recommended developer, and with this also no ammonia fumes are flying about to distress your ophthalmic as well as your olfactory organs.

The advantages in the printing of transparencies is well known to many in this club, and those members who have used hydroquinone for this purpose will support me in bringing evidence to its freedom from deposit as well as stain; we have none of the creamy deposit of oxalate of lime arising from the employment of ferrous oxalate nor the yellow stain from the use of pyro; the slide comes out of the developer perfectly clean glass, but, as the alkalis are rather difficult to remove, it is necessary that the transparencies should be passed through a bath of alum and citric acid before their final washing, as if this is omitted the plates bear a streaky appearance when dry. With regard to the exposures necessary with hydroquinone-developed plates, if I may judge from photo-micrographic work, it appears to me that we may give a very full exposure without any detriment to the quality of the negative. It has not been possible at this season of the year to try it on instantaneous work, but should it be tried later on I think the hydroquinone must be increased to a very full extent; a developer weak in hydroquinone is very slow, but by increasing its proportions it becomes as manageably rapid as pyro. We trust the next season will enable us to put this new agent on its trial, when I believe, unless I am too sanguine, that it will be weighed in the balance and not found wanting in the good characteristics I claim for it. If we should find it lacking in the good qualities we are so familiar with in pyro, I will fully retract, and throw up my brief.

The formula I have employed, and with whose results I am well satisfied, is that given in the direction for developing Thomas's lantern plates, but I find that it requires slightly strengthening with more hydroquinone to make it conveniently quick in its action when used upon ordinary negatives. Negatives developed with hydroquinone fix very quickly and thoroughly, as this developer has not the tanning action on the gelatine which pyrogallie acid has, consequently the film is more pervious. There is a very unusual precipitate formed in the fixing bath in the shape of a greenish-brown finely granular deposit, unlike anything seen with pyro, but of whose nature I am not chemist enough to tell you any particulars. I only call attention to it to warn those who may be led to fix albumenised prints in the same dish that as had this deposit in, to see that the dish is well cleaned with hydrochloric acid before it is used for fixing prints, as I recently had about a dozen prints hopelessly stained yellow from neglecting this cleanly precaution.

Hydroquinone may also be used for developing any of the bromide papers. I have lately been trying it on Morgan & Kidd's, and also on the Eastman paper with about equal results—that is, I found a very decided yellowing of the whites, which was most annoyingly prominent when the prints were dry. I have succeeded in doing away with that by immersing the print in the acetic acid bath recommended for clearing the Eastman paper after the iron developer, and it seems to remove it almost entirely.

The formula used is stated to be unusually and unnecessarily strong, but I have preferred taking it as I found it, instead of going out of my way to try and improve upon it. I have not the time for experimenting, or I dare say other and more favourable modifications might be arrived at. Hydroquinone is on its trial at the bar of the photographic world, and I close my pleadings in its behalf by asking you to believe that I am honest in all I claim for it.

(Discussion in our next.)

THE CONSTRUCTION OF PHOTOGRAPHIC LENSES.

This paper, which was read at the Society of Arts by Mr. Conrad Beck, appeared in our last and preceding issues. The discussion was as follows:—

The CHAIRMAN (Mr. J. Traill Taylor) said two years ago he addressed an audience in that room on the characteristics of the lenses then in existence, without any regard to theory. Mr. Beck had discoursed on the theory, so that in this case practice certainly went before theory. Mr. Beck said that a concentric lens had hitherto been an impossibility, as, if quite concentric, it would not have the required refraction. But some two or three years ago he examined one in which, so far as he could learn, the lenses were concentric. It was made of a glass of an exceedingly high index of refraction—some of the new Jena glass—and projected the oblique pencil practically perfectly on a flat plane. The aperture was somewhat small, however—about f.16. Some difficulty arose in obtaining the right kind of glass, but it was consoling to know that such a thing had been done. Mr. Beck had suggested a spherical lens as one which, if obtained, would give marginal definition on a curved plate; but many years ago Mr. Sutton made a lens composed of a shell of fairly dense flint glass, filled with water, and an ingenious diaphragm placed in it. It was a panoramic lens, embracing a wide angle. The plate was curved cylindrically, and the spherical aberration was very well corrected—sufficiently well, at any rate, to enable one to enlarge a picture taken with it two or three diameters.

Mr. T. H. DALLMEYER said he did not quite follow Mr. Beck in what he said about theoretical men. They were in many ways indebted to Sir George Airy's treatise on spherical aberration, and he afterwards annexed it up in a practical form for opticians who did not understand the subject. Only a day or two ago he was looking over a paper by the late Peter Barlow, who worked with Dollond, and he there said, in a particular instance in which he described a negative achromatic eyepiece, that although he gave the formula, opticians as

a rule had to sacrifice a very great deal of mathematical elegance to the utility of practical observation. When you had theoretically arrived at the main principles to work upon, a man used to observing the character given by the principles—in such as the image, and so on—would know in what direction to lean—so that he could gain anything through a calculation of the excentric pencil. The excuse made for the mathematical men not going into the subject was that it was too cumbersome; there was no prettiness in it. The results were laborious, and when obtained you gained very little information which you would not obtain better by a little practical effort after first arriving at the approximate result theoretically. With regard to Jena glass, he had one or two specimens which were very full of colour, and the surfaces were not to be relied upon, so that he had not done much with it. However, on high authority, such as Dr. Vogel, they were told that these lenses were very successful, and as he did not think English opticians ought to be behind, he was working on the same subject.

Mr. J. WARNERKE asked if it were possible to have lenses suitable for orthochromatic photography, viz., with a coloured part added, in order to avoid the use of screens, which generally very much affected the sharpness of the image.

The CHAIRMAN said he presumed the question would include colour, either in the glass itself or in the cementing balsam, to act the part of a screen in orthochromatic photography. Captain Abney had suggested the application of coloured collodion to one surface of the lens.

Mr. WARNERKE said he had come to the conclusion, from his own experiments, that the use of the screen, either in front, behind, or between the lenses, and no matter how carefully prepared, spoiled the image.

Mr. DALLMEYER said no doubt that would be the case. If you looked directly through the parallel surface of the glass there was no effect on the position of the image, but if you looked obliquely through a parallel ray it was certain to be displaced. Captain Abney's plan, therefore, would be preferable if the colouring matter were applied equally to the surface. It struck him the other day that perhaps the best possible form would be a coloured glass, if it could be obtained homogeneous, placed parallel to the surface of the outside lens, and then possibly the rays coming in any direction would not suffer—but he was only speaking off-hand.

The CHAIRMAN remarked that history repeated itself. This plan had been suggested before Mr. Dallmeyer was born, by Emil Busch, in a very old treatise on photography. But in this case, the blue glass shell was for the purpose of obtaining the actinic effect.

Mr. BECK thought it must be obvious to every one that if the glass of the lens itself were coloured there would be much more colour in the thicker part than in the thin. If you had a parallel plate of glass, the same lens would always have to be used with it, as it would alter the corrections.

Dr. LINDSEY JOHNSON asked for a definition of two words which one often met with, which he had seen used with quite different meanings. Dr. Monckhoven stated that an aplanatic lens was one which could be used with the full opening, and that an antiplanatic one had to be stopped down in order to get definition at the sides. On the other hand, Dr. Eder gave an absolutely different definition, saying that an aplanatic lens was one in which the two systems—the front combination and the back—were almost similar; whereas in an antiplanatic lens they were totally different, as in a portrait lens. The first definition seemed to him totally absurd, as you had only to cut down your lens sufficiently, as in one of Ross' portable asymmetrical ones, and you had at once an instrument which could be used with full opening; yet if it were not cut down to small circles, instead of what Dr. Monckhoven would call an aplanatic lens, it would be an antiplanatic. In no book could he find an authoritative definition of these terms.

Mr. LYONEL CLARK said he understood Mr. Beck to mean by astigmatism spherical aberration of the oblique pencil, and he should like to know what difference there was between that and coma. If it were the same, it would somewhat simplify a rather troublesome correction. He was much pleased with the attack on examination papers, and the absurd mathematical way in which the simplest problems were obscured. One reason, probably, was that examiners were nearly always chosen from those who wrote books, and, consequently, those who went up for examination had mainly to find out what marvellous terms his examiner had happened to use. With regard to coloured glasses, as Mr. Beck had pointed out, it was practically impossible, and certainly not desirable, to tint the glasses themselves, on account of the different thicknesses of the refractive surfaces; but in a discussion on the same point some time ago, it was mentioned that it would be quite practicable to use a method which had been employed by the Chairman for a different purpose—to take two ordinary glasses, a positive and a negative, exactly correcting each other, and cement them together with coloured balsam.

The CHAIRMAN said there was another objection to the Jena glass besides the colour, which had been already mentioned, and one which seemed fatal. That was the stability of the surface, after it was polished, to disintegrate or rust, as he might term it. A distinguished London astronomer had a prism from abroad, made of a very suitable kind of glass, but after a short time it was found that the surface got rusty. He then had it cleaned and polished, and encased within parallel plates of harder glass, and it then became utilisable. If a glass of this sort were employed, as Mr. Dallmeyer employed the flint glass in his treble single combination, some benefit might arise; but he thought the Jena glass would bear a good deal of improvement before it could be used

as ordinary glass. A method of applying colour in connexion with spectacle glasses was patented some years ago, consisting of putting a film of coloured balsam or varnish between two surfaces of glass ground to the proper curvature. He did not know that they were much used, but he remembered seeing a lot of them sold off by auction not very long ago.

Mr. J. R. GOTZ said as far as his information went, an aplanatic lens was one free from spherical aberration, which brought the rays to a focus on a plane. The question arose next, with what portion of the aperture did it do that. Photographers required a large aperture, and the answer would be that when a lens was satisfactorily aplanatic, it was so with a large aperture. Almost every lens could be so with a small aperture, but a well-corrected first-class lens should be aplanatic with a large aperture, and that was the direction in which Continental opticians had been working. The antiplanat was simply a description of the form of the lens. The firm which brought out the so-called antiplanat required to bring something new before the public, and, as far as he could understand, the term simply applied to the form in which it was ground. With regard to the Jena glass, he thought there was a good deal of piecemeal information about, which gave it a character which it only partially deserved. Some of it was exactly the same as glass produced before by eminent firms, and would show the sodium and other lines coincident with it to about the third or fourth decimal. Such glass, of course, might replace that which had been used hitherto perfectly well, as it could not be any more susceptible to atmospheric influence. There were other kinds, which were exceedingly white. For instance, there were some light flints which would almost replace the heavy flints, and with great advantage. The Jena people offered to make glass for opticians, giving any refractive index they required, or any required dispersion, and if they could do this, it was hardly right to complain of what they did. The establishment of the manufactory had been preceded by a good deal of research, which was supported by the Prussian Government, who found Messrs. Schott the necessary funds to make every possible experiment, and at last the experiments were completed, and the factory was established under the protection of the Prussian Government. He thought it was a great credit to them, and that when these glasses were better known their value would be more appreciated.

Mr. CHAPMAN JONES said he had seen several examples of the Jena glass, but only one was affected by the atmosphere to any appreciable extent, and they were all remarkably free from colour, much more so than most flint glasses. In a depth of four or five inches one might almost call it colourless. With regard to the use of coloured screens, he thought it possible, by putting the screens either in front or behind the lenses, to cure curvilinear dispersion in a single lens.

Mr. THOMAS S. TAYLOR, while thanking Mr. Beck for his interesting paper, thought there was one matter he had somewhat overlooked. He said that to cure astigmatism it was necessary to have lenses of deep curves, but he ventured to think that that was a misapprehension. What he meant by astigmatism in a lens was that the oblique pencils were practically what was known as the circle of least confusion. He should put the matter thus:—To obtain a flat field in a photographic lens, to make the rays at the edge of the plate to coincide in the same plane with those in the centre, deep curves were necessary. It was possible to obtain practically no astigmatism in a lens which gave a very concave field. If you got the centre in focus, with no astigmatism, and then pushed the glass a little further in and focussed the edge, you had very little astigmatism, if the lens had flat curves; but if it had deep curves, you had the maximum astigmatism. Therefore, he came to the conclusion that it was impossible to have a flat field together with freedom from astigmatism; the two were physically opposed, just as depth of focus and length of focus were. Mr. Beck had possibly overlooked one fact when he said that it might be possible with the Jena glass to make lenses perfectly concentric. If so, the convex surface of the lens would be flatter than the concave, and therefore it would minify, not refract, the concave surface being of shorter radius. This might be overcome, possibly, by a difference in density, but as the lens was designed the denser one must be the convex one, with the concave surface inwards. He concluded, therefore, that astigmatism and flatness of field were physically opposed to each other. He fully agreed that Mr. Beck had done good service to optics, and to science generally, by his none too strong remarks with reference to examinations, and the impractical and useless application of formulae in such examinations. With reference to the Jena glass, Mr. Gotz had referred to the possibility of any optician obtaining exactly what glass he required on giving the refractive index and the dispersion; but he (Mr. Taylor) thought that was the weak point in what the company proposed, because it seemed to him that so many different qualities would be produced, that it would be impossible to rely on getting two or more batches exactly the same. In England there were only a limited number of qualities obtainable, and therefore the quality was kept regular; and unless it were so, it would be necessary to recalculate the curves for every batch of glass.

Mr. BECK, in reply, said the Chairman had referred to a globe lens, which he thought was the same as he had mentioned as having been tried and discarded.

The CHAIRMAN said he referred not to the so-called globe lens, as formerly employed in America, but to the panoramic lens of Mr. Sutton, which was designed and manufactured in London; it had a perfectly spherical shell of glass, which was filled with water, and a diaphragm was fixed in it. The American globe lens (which he sketched on the board) was of an entirely different construction.

Mr. Beck said he had meant to refer to Sutton's lens. The other was not really concentric, because it was made of ordinary glass. There was immense room for the mathematics in connexion with optics to be written better. No one who had read such books as Parkinson's, and the ordinary mathematical books on optics, could help seeing that they were atrociously bad. Even Heath's book, which came out about a year and a half ago, although it was a magnificent work in many ways, had this defect, that he defied any one on reading it the first time to say how he reckoned his signs. With reference to the words *splanatic* and *antiplanatic*, he only considered them names for a particular form of lens, more of a commercial character than anything else. He took *splanatic* to mean freedom from spherical aberration, which did not mean giving a flat field necessarily. A great deal had been said about the Jena glasses, and some one had mentioned forty-five different kinds. He had particulars of over ninety kinds, and had samples of, perhaps, forty, and some of it was equal in every respect to what they were in the habit of using, and, in fact, it was just the same; but some would not stand exposure to the air, and the great difficulty was that just those kinds which they wanted to use were those which would not stand exposure. Those which had the extraordinary qualities which would make it possible to do what Mr. Thomas Taylor seemed to think impossible, were those which would not stand exposure properly. Mr. Taylor doubted the possibility of making concentric lenses which should be refractive and not give a minus effect, but he had thirty or forty lenses at his factory, which he should be glad to show him. He thought he was under some misapprehension about astigmatism. It meant the aberration of rays in passing obliquely through a lens, so that they did not come to the same point. When you had got the rays to meet, then came the question of flatness of field. If you corrected astigmatism you had a curved field. To perfectly correct flatness of field was largely a question of stopping down; but there seemed to him no impossibility in perfectly getting over the difficulty. It was said that it had been done in Germany, but whether that was so or not time would show.

The CHAIRMAN then proposed a vote of thanks to Mr. Beck, which was carried unanimously.

FIFTY YEARS' PHOTOGRAPHY.

[A Communication to the Glasgow Photographic Association.]

By general consent it is agreed that the science, whose aims and purposes we, as an Association, seek to further and advance, has at last reached its period of jubilee. At this stage in the history of photography it may not be without interest to take a retrospective look, and see from what comparatively small beginnings the science and art of photography has arisen. Many of the earlier facts and triumphs have been lost sight of in the perfected processes of our own time, and are indeed unknown to the ordinary worker of the present day. In the paper which it is my privilege to bring before you this evening, it would be perfectly impossible, having regard for the time at my disposal, to lay before you the complete record of what has been done during the fifty years' existence of photography; I can only refer to the more important points, and it will be my endeavour to do so in a way that may not be deemed wearisome by those who may be present this evening.

We have it on the authority of the poet Laureate that—

"Science moves but slowly, slowly creeping on from point to point,"

and perhaps a good confirmation of this may be found in the fact that the camera obscura existed for nearly three hundred years before a method was found whereby the pictures obtained in the darkened chamber could be rendered permanent. The name that has been associated with the camera is, as most of you are aware, that of John Baptista Porta, a neapolitan philosopher, who flourished in the sixteenth century. Eder, in his *Handbook of Photography*, is inclined to attribute the discovery of the camera to a Benedictine monk, one Panthus, but be this as it may, certain it is that Porta in his *Magia Naturalis*—*Natural Magic*—describes the method of obtaining images in a darkened chamber. In the first edition of this work reference is made only to a simple aperture, while in the later editions the use of lenses to improve the appearance of the image is recommended. A word or two regarding Porta may not be out of place. First of all we will throw upon the screen his portrait, taken from the frontispiece of one of his works, *De Humana Physiognomonica*, published at Sorrento in 1586. I was fortunate enough to secure a copy of this very rare first edition at the sale of Lord Crawford's library.

Porta seems to have been born at Naples about the year 1550. At a very early age he appears to have shown great delight in studying the works of the old philosophers, and it is recorded that when he was ten or eleven years of age he was able to compose in Latin. Brought up under the care of an uncle who fostered the natural tendencies of young Porta, we find that he travelled through France, Italy, and Spain, his principal object being to consult the various libraries scattered throughout these countries, and make himself acquainted with the contents of the old manuscripts collected together in the different storehouses of learning. Porta, on account of a Society which he founded and named *De Secreti*, found himself in discord with the Pope of that day, Paul III., and he had to betake himself to Rome in order to justify the action, and this presumably he would have no difficulty in doing, as the Society was only intended as a means for encouraging the natural sciences, the members for which were only eligible who had done something in the way of discovery, either in the

art of medicine or in natural philosophy. Porta, along with his brother Vincent, established a museum of natural curiosities, which was visited from time to time by the men of science from other countries. Porta never married. He died at Naples in the year 1615. His writings were varied. We have already referred to his *Natural Magic*, it was originally published in four books, but subsequent editions contain twenty books. Several of these contain as frontispiece a portrait of Porta standing in front of a concave mirror, with a sword in his hand performing the experiment known as the mysterious dagger. We will throw on the screen the picture in question, which is taken from a copy of *Magia Naturalis*, published in Amsterdam in the year 1664. The original work I have brought with me and can be seen by the members at the conclusion of the paper. I have also a copy of an early edition published by Plantin, of Antwerp, in the year 1585, which contains only the four books. I may mention an English translation has been published bearing date 1669. I regret that so far I have not been able to procure a copy of this translation. I may, however, give a few quotations from the seventeenth book of this translation, which bears more especially on Porta's experiments with his darkened chamber, and the employment of a lens. After describing the way "to see all things in the dark that are outwardly done in the sun with the colours of them," he adds: "Now will I declare what I ever concealed until now, and thought to conceal continually. If you put a small lenticular crystal glass to the hole you shall presently see all things clearer, the countenances of men walking, the colours, garments, and all things as if you stood by: you shall see them with so much pleasure that those that see it can never enough admire it." He further recommends, "But if you will see all things greater and clearer, over against it set the glass, not that which dissipates by dispersing, but that which congregates by uniting both by coming to it and going from it, till you know the true quantity of the image by a due appropriation of the centre, and so shall the beholder see more fitly birds flying, the cloudy skies or clear and blew mountains that are afar off, and in a small circle of paper (that is, put over the hole) you shall see, as it were, an epitome of the whole world, and you will much rejoice to see it." The quaint descriptions of a concave and a convex lens are well worth noting, that which dissipates by dispersing and that which congregates by uniting. Porta further suggests the use of the darkened chamber as an aid to drawing. He says:—

"If you cannot draw a picture of a man or anything else, draw it by this means, if you can but only make the colours. This is an art worth learning. Let the sun beat upon the window and then about the hole; let there be pictures of men that it may light upon them but not upon the hole. Put a white paper against the hole, and you shall so long pit the men by the light, bringing them near, or setting them further, until the sun cast a perfect representation upon the table against it; one that is skilled in painting must lay on colours where they are on the table, and in the superficies it will be seen as an image in a glass."

The camera obscura was at one time a much more popular affair than it is now. It formed often one of the features of country residences. The diagram thrown on the screen will give a good idea of the form in which the camera obscura was erected.

Before we pass on, however, I may refer to the general writings of Porta, and the titles of his various works; these are:—A treatise on cipher writing, entitled *De Furtivis Literarum Notis*; one on plants, *Phytognomonica*; another on the relations supposed to exist between men and animals, *De Humana Physiognomonica*; it might be interesting to show the mode in which this work has been illustrated. A transparency from one of the cuts will therefore now be shown. It represents the head of Socrates alongside a stag's head, the point of similitude as in the flat noses. Porta has a work bearing on agriculture, cultivation of trees, &c., and its title is *Vallia*; another relating to optics, *De Refractione Opticæ parti libri III.* He wrote concerning hydraulic engines, *Pneumaticorum libri tres*; another work, *De Cælesti Physiognomonica*, treats of the heavenly bodies. *Ars Reminiscendi* is a compendium of all the methods made use of by the ancients to aid and strengthen the memory. A book regarding distillation, *De Distillatione*, which gives one a good idea of the state of chemistry, or rather alchemy, in the sixteenth century. A treatise on fortifications, *De Munitione*; and the last of his scientific works, *De Aeris Transmutationibus*, which may be reckoned the first work bearing on meteorology. Porta towards the end of his life took to writing plays, and four comedies and two tragedies emanated from his pen. Enough has been said regarding our philosopher to show how varied must have been his talents, and although much that is inaccurate and even childish is to be found in his writings, we have yet to remember that he lived in an age of superstition, when alchemy and astrology were regarded as sciences. The only other two works which I possess of Porta's are two editions of his cypher-writing, the first edition published at Naples, 1563, and a later one published at Montbelliard, a town in France, in 1593. These, with those previously mentioned, can be seen by any interested at the conclusion of my paper. In anatomy Porta's name still lives, for anatomists still speak of the Vena Porta.

It is difficult to say to whom we should attribute the camera obscura in its portable form. Robert Hooke, a famous English mathematician describes such an apparatus in 1679, and Mario Antonio Cellio, in 1687, recommends this form of the camera for assisting artists. In the transparency now shown you have a reproduction of the illustration which is found in Hooke's *Philosophical Experiments*, where this device of his is

described. This work was published in 1726, and the original copy I have with me.

Photography may be said to be the offspring of the two sciences—optics and chemistry. We have just been considering the parentage on the optical side, and perhaps on the chemical we might have to go still further back in the annals of history were it desirable to be minute; but one thing is certain, that at all events in Porta's time the darkening of silver chloride by the action of light had been observed by the alchemists. The name by which this substance was then known was that of horn-silver—*luna cornea*; and the alchemist, Fabricius, in his work, *De Rebus Metallicis*, printed in 1564, gives a lengthened account of its various properties. It was reserved, however, to the famous Swedish chemist, Scheele, to give, in 1777, a philosophical explanation of this darkening action of light, and he showed that the action took place more rapidly in the violet-coloured rays than in any other. Coming now to the beginning of the present century we find that Ritter established the fact that the rays beyond the visible spectrum had even a greater action than the visible. The names associated with investigations of a similar nature at this period may be just simply given, Sennebie, Seebeck, Dr. Woolaston, Sir Wm. Herschel, and many others.

In France, a Professor Charles was in the habit of showing to his class about this time a mode by which portraits of a kind could be obtained by the darkening action referred to. The picture now shown will indicate his manner of proceeding. Strong sunlight was allowed to penetrate through a considerable aperture in a darkened chamber, and where the light fell the sitter was so placed that the profile of his head cast a shadow on the paper behind him; a sort of silhouette was thus obtained, but as no mode of rendering it permanent was forthcoming it was valueless.

Thomas Wedgwood, fourth son of the Wedgwood of porcelain fame, as also Sir Humphrey Davy, occupied themselves with the attempt to secure light-drawn pictures. Beyond establishing the fact that the chloride was more susceptible than the nitrate of silver, and that white leather as a basis for the image gave better results than white paper, the problem of fixing remained still unsolved. These two investigators did not attempt camera pictures, they contented themselves with what we would now call printing by contact. This was in 1802. We come now to the year 1814, and the man who was destined to secure the first permanent picture appears on the scene—Joseph Nicéphore Niepce. He, too, seems to have started in the first instance experimenting with the salts of silver. Discarding these, he studied the action of light on resinous and bituminous bodies. He devised a process, to which he gave the name of heliography, which was based on the fact that a substance known as bitumen of Judea after exposure to light was no longer soluble in the menstrua which originally dissolved it. Application of the process now known as the bitumen process remains to the present day, being made use of in certain photo-engraving processes. Niepce employed pewter plates covered with the sensitive bitumen. Comparatively sensitive in the case of contact printing, the material was by no means sensitive enough for camera work, hours being required to effect the necessary change in the camera. Pictures are, however, extant secured by this means, and some little time ago I had the honour of bringing one before our Association. A few facts connected with Niepce's career may not be without interest. He was born at Chalons-sur-Saône, March 7, 1765. Educated for the Church, he, however, ultimately became a soldier, and saw actual service. Retiring from the army on the score of ill-health, he settled down at Chalons. His leisure time would seem to have been devoted entirely to experimenting, and we may take it that it was about the year 1813 he commenced those experiments which ultimately ended in his heliographic method. A good deal is learned regarding Niepce's work from a French book, *La Vérité sur l'Invention de la Photographie*, a biographical notice by Victor Fouqué, published in the year 1867. The book in question is rarely to be met with now, but I have a copy, which can be seen further on. Nicéphore Niepce had a brother, Claude, and the book is largely made up of the correspondence which took place between the two brothers. Claude seems to have had also an inventive turn of mind, and he came over to England regarding a machine of his, the "pyrelophore"—a method of propelling vessels by means of hot air. This was about the year 1811. Nicéphore visited his brother at Kew in 1827, and he then wished to bring his process before the Royal Society. On account of his not divulging the method his memoir was not received by the Society. At the opening meeting of last session we had that identical memoir before our Society, as also a reproduction of an engraving and the camera picture already referred to. Niepce would seem to have worked hard all his life at the attempt to secure light-drawn pictures, but success did not crown his efforts. He died at the age of sixty-eight, his death occurring on July 5, 1833.

Four years previously Niepce had entered into partnership with Daguerre, and we will throw upon the screen a portion of the facsimile of the now world-famous copartnership, that portion containing the signatures of the respective contributors. Fouqué's work has the complete deed reproduced, but we have thought it sufficient for our purpose to show the particular portion referred to. Daguerre, although a Frenchman, may be said to have added a word to our English vocabulary. Although many may not exactly comprehend what a Daguerreotype really is, few there are who have not heard the term. A few details regarding Daguerre, and how he became associated with Niepce, may be here given. This photographic pioneer rejoiced in a perfect plethora of

names—Louis Jacques Mandé Daguerre. His portrait, taken from a Daguerreotype by Mayall, in 1846, is now presented to you. Daguerre was born at a village near Paris, named Cormeilles, on November 18, 1787. He seems to have been left at an early age to his own resources, but appears to have developed a considerable talent as a scene painter. He was employed as scenic artist at several of the theatres in Paris. Daguerre originated those scenic effects known as dioramas. A diagram illustrative of Daguerre's pictures and his mode of showing them is here reproduced. The pictures were painted on both sides of the canvas, and shown first by reflected and afterwards by transmitted light. A description of the mode of producing such pictures is to be found in a translation of Daguerre's treatise on Daguerreotype published in London in 1839.

I have with me this evening the translation referred to. Daguerre's Diorama was one of the sights of Paris. It was opened in the year 1822, and continued till the year 1839, when it was destroyed by fire; this occurred on the 3rd of March in the year specified. The subjects he had in this manner portrayed on canvas were many and varied—*Roslin Abbey in a Fog*, changing afterwards to a snowstorm; *The Deluge*; *A View of Paris from Montmartre*; *Napoleon's Tomb*, *St. Helena*; *Princes-street, Edinburgh*, and *A Fire*, &c. The Temple of Solomon was his last production.

In his sketches from nature Daguerre is said to have largely made use of the camera obscura; and to fix the ephemeral images of the instrument seems to have been the one idea of the illustrious Frenchman. So engrossed with what he deemed possible did Daguerre become, that the story is told of his wife consulting some of the scientific men of the day regarding the sanity of her husband, and receiving the reply that the thing Daguerre sought after was not by any means impossible. We rather think that Madame Daguerre would not derive much comfort from an answer such as this. It may be here mentioned that Isidore Niepce, the son of Nicéphore, took his father's place in the Niepce-Daguerre copartnership, which was to last for ten years, starting from 1829.

W. LANE, JUN.

(To be continued.)

THE USE OF COMPRESSED GASES.

THE publication of the complete evidence in the case of the lamentable Dublin explosion has undoubtedly given a thrill of relief to many whose confidence in the security of the useful gas cylinders had been somewhat rudely shaken by the first accounts. True workers of experience waited before forming any opinions, knowing, or rather feeling sure, that when the truth was known some circumstances would be found which would explain the occurrence, without detracting from the security generally felt when proper care and experience are brought to bear. But old hands were puzzled. Even such an operator as Mr. Chadwick cannot help showing it. It seemed impossible to suppose that a man, apparently conversant with the matter, should expose himself to the danger of experimenting with a cylinder of "mixed" gas. But the apparent impossibility has proved to be the truth, and, what most would have anticipated, turned out to be the actual result. Given a cylinder of mixed gases in a room with some one who avowedly went in to "experiment" with it—"experimenting" necessarily meaning trying how it would burn—and it needs no special evidence to account for the explosion and the fire; indeed, had no explosion taken place, all settled ideas as to explosive gas would have been upset.

But one or two points arise on which questions may be asked. The deceased gentleman is reported not to have considered the mixture dangerous, because the quantity of hydrogen was small as compared with the oxygen. Let all experimenters be warned that no quantity of hydrogen is too small to become explosive in the presence of oxygen. On the other hand, the quantity of hydrogen may be too large to be dangerous, seriously that is; but such a mixture as existed in the Dublin case could only be, as it proved, most violent in its combustion and results.

Another question is, Why did it not explode at first when tried by the customer, and afterwards on its return to the works? This is easily explained. When the cylinder was fully charged, the valve would be opened to such an infinitesimal extent, that flame, though "snapping" in the pipes, could not pass back into the cylinder; later on, as the pressure decreased, and the valve would be opened more, a "flame-way" would be created, and the explosion would result.

It will be seen, therefore, that no discredit is cast by this case on the use of compressed gases, and that the cylinder was not in any way at fault. Various suggestions have been made as to the desirability of a government test for such cylinders, and as to making the commercial mixing of such gases penal, and it may be well in a few words to examine such suggestions.

First, the desirability of a government test. No such test would have prevented the explosion under consideration, and there is no case on

record of a cylinder failing through weakness. It is well known that Brin's Oxygen Company will not charge strange cylinders without previous testing, for which they charge, I believe, one shilling, and it is within the power of all who use their own cylinders to have a guarantee of test by the makers. My own cylinders, and I would never use bags, or make my own oxygen again, are guaranteed by the makers as tested to two tons to the square inch, and as the full charging pressure is one hundred and twenty atmospheres, or considerably less than one ton, the margin of safety is ample. Further, if a cylinder has properly stood the test of charging and transmission, it is not likely to burst in use when the pressure is all the while diminishing. This element of danger may safely, therefore, be left for makers and compressors to deal with, without any need for government interference.

On the question of special legislation for "mixed" gases, there appears little need for any amendment of the existing law, as the dealer who sent out mixed gas for oxygen or hydrogen would certainly find himself on trial for manslaughter if death were caused thereby, and liable for damages if the only consequence were destruction of property—a liability quite as strong in prevention of carelessness as any direct legal penalty.

The lesson of the explosion seems to be that no more danger need be looked for in the use of gas in a compressed form than in the bags, at least not as arising from the cylinders or the compression, while in the opinion of many the advantages are all on the side of the portable form; while another lesson is that neither gun-cotton, dynamite, chlorate of potash compounds, nor the limelight, are things to be handled without due and proper care, and a reasonable knowledge of their nature and peculiarities. All these things are safe in careful hands, all these things, and many others, are dangerous in careless hands; and there are few operations which prove the truth of the proverb, "Whatever is worth doing, is worth doing well," more completely than those connected with oxyhydrogen lighting.

Some of the suggestions in Mr. Chadwick's article in last week's JOURNAL are most valuable, and although to some extent already anticipated in current practice should be insisted on with persistent iteration until the practice becomes universal. I allude to the proposal that in all cases a distinctive colour should be adopted for gas cylinders, say black and white, or better, black and red, for oxygen and hydrogen respectively, and that in all cases the contents should be distinctly and unmistakably marked on the outside. The idea of altering the fittings so that it should practically be impossible to fill incorrectly is good, but would, I fear, cause too much disturbance to existing conditions of trade, as all the present stock of cylinders would have to be taken over by oxygen, and new cylinders, and all connected with their filling, made for hydrogen, which hardly seems practicable. Distinctive colours and plain marking ought to be quite sufficient for ordinary care, which is all that should require to be legislated for. B.

LETTER FROM GERMANY.

A Quick Printing Process—Results with the New Optical Glass from Jena—Concentrated Hydroquinone Developer—Influence of the Developer on the Colour of Prints—Caustic Potash in the Developer.

Many times (writes Dr. Vogel in *Anthony's Bulletin*) I have heard professional photographers ask the question: "What can I do to furnish in two days 1000 prints from one negative?" If I reply, Take bromide of silver paper—the answer will certainly be: "That gives black pictures, but I want them brown like regular photographs." Well, this could be very easily accomplished with the aid of Lichtdruck (cottonotype). But good cottonotypes are not to be had everywhere. We have now a process admitting very well the solution of the problem, and which can be executed by every skilful photographer. It is nothing more or less but the use of chloride of silver gelatine paper. This paper has been known for years, but has met with less favour than it deserves. By way of a test I gave director Helf, in Jüdenburg, an order to develop 1000 copies upon chloride of silver gelatine paper.

Mr. Helf writes:—"The copies you sent me were printed in the hand copying apparatus (Patent Schlotterhaus) on roll paper, in diffused daylight, seven seconds. Total time, two and a half hours."

The rolls were cut in strips of four pictures each; duration, two hours; they were then developed with oxalate of potassium, 3; sulphate of iron, 1 (saturated solutions); diluted with some quantity of water, and with moderate addition of bromide of potassium.

The developer keeps from fourteen days to one month. Four strips of four pictures each were worked at one time. Time, three minutes; therefore total duration of development for one hundred pictures about four hours. After this they were well washed and fixed two minutes in lots of forty; therefore altogether one hour. After this they were washed for two hours in repeated changes of water.

The toning was done with twenty copies at a time in the sulphocyanide

gold bath. It was finished in about four hours. After this the pictures were washed for one minute and put into the alum bath together about one hour. This was followed finally by washing, squeezeing upon glass with a rubber roller, and drying by artificial heat (two hours). During the summer season this is done best in the open air in sunshine.

The squeezeing requires about four hours for 1000 copies. This time is calculated for one person, with extra help the time can be reduced to one half.

The tone is according to one's pleasure, but it is difficult to obtain perfect equality in large quantities, because the intensity of daylight changes during printing. This is no hindrance for practical purposes.

The pictures are trimmed with the glass pattern. The mounting requires practice and care. Glue is spread in the middle of the cardboard (very little, to prevent it from running out on the sides), and the picture is placed on a large glass plate and glued on the edges; but great care has to be taken that the glue does not touch the picture side. In mounting, the glued parts of picture and cardboard will meet.

Each picture is laid upon a fresh part of the glass plate, and when this is full another one is taken; the first one used can be cleaned and dried in the meantime. With a little practice and working in concert, one hundred and fifty pictures can be mounted in an hour by two persons without injuring the glass in the least. The material used for pasting has to be a pretty thin glue. The pressing on to the cardboard has to be done with a rubber roller. After drying, the picture is burnished (cold). Retouching is done from colour with gum arabic.

Since the establishment of the new factory of optical glass of Schott & Co., in Jena, a change is coming in practical optics, therefore also in the production of photographic objectives. Until now all opticians of the world were obliged to procure their glass from Paris and Manchester. Unfortunately, these were not always uniform, and the lens calculations made for one lot would not always agree with those for the next shipment. This has ceased now. The glass factory in Jena is under a scientific management, and one fusion is exactly like the other. The opticians do not require any more to remodel their polishing trays, for each new shipment and the glass furnished is of such uniform proportions not thought of as attainable in former times.

Our first-class opticians, Voigtlander in Bromswig, and Steinheil in Munich, are occupied with testing the new glass, assisted by two scientists of the Imperial Physical Institute, Dr. Lummer and Dr. Kaempfer. The first result of their activity I obtained recently from Voigtlander, in the shape of two eyescopes of exactly the same focal distance. The difference was surprising. With full opening the one will cover a visual field of fifteen cm., completely sharp, whereas the other will cover only eleven cm. This is of great importance for portraits and instantaneous views. The luminous circle of the new objectives was also about four cm. larger than that of the old ones. This is of great significance for the production of wide-angle lenses.

The results obtained characterise sufficiently the progress which has been made with the new glass of Jena.

The movement in favour of the hydroquinone developer proceeds quietly. My son made the observation recently, how, with different mixtures of hydroquinone, with carbonate of potassium or sodium, the colour of the paper pictures (bromide of silver paper) made with the same can be considerably influenced. This colour depends upon the quantity and the kind of the salt added. If the developer is made according to the following formula:—

Sulphite of soda (crystals)	40 grams.
Hydroquinone	5 "
Carbonate soda (crystals)	50-150 "
Water	900 c.c.

Green pictures will always be obtained up to seventy-five grams carbonate of soda. At a larger soda proportion the tone will gradually improve to black or brownish black.

With seventy-five grams of carbonate of soda and correct exposures good results can be obtained, but not with over exposure.

Carbonate of potassium has the great advantage over soda, that the pictures will never have a green tone, and it is therefore decidedly to be preferred for the development of paper pictures.

My son composes the developer as follows:—

Sulphite of soda (crystals)	40 grams.
Hydroquinone	5 "
Water	150 c.c.

After everything has dissolved (if necessary, by putting the bottle in hot water), fifty to fifty-four grams of carbonate of potassium are added. A larger quantity of carbonate of potassium will easily cause strong formation of bubbles during development, particularly in hot weather. For use, five c.c. are diluted with water to thirty c.c.

This concentrated developer keeps a very long time (in diluted condition only two to three weeks) and can be recommended particularly for travelling. In the development of gelatine plates I obtained with the same also very good results; it might also be recommended for instantaneous views, producing a great many details and causing a very rapid development.

For the negative process I prefer in most cases the soda developer. On

account of its greater durability it can also be kept in the following concentrated form:—

Sulphite of soda (crystals)	40 grams.
Hydroquinone	5 "
Carbonate soda (crystals)	75 "
Water	200 c.c.

For use, dilute ten c.c. with water to thirty-five c.c.

Both developers can be graded according to the character of the plates to be developed or the desired result; for too hard working plates less water is used for the developer, and more water for soft working plates.

The price of the hydroquinone developer might prove to be considerably cheaper in the form mentioned (even if used for one development only) than that of the pyrogallol developer.

Several authors recommend an addition of caustic potassium or caustic soda. I do not feel much inspired about it. True enough, it accelerates development, but it causes slippery hands and easily gives cause to frilling, particularly in the summer. I remark, besides, that the development with carbonate of potassium and correctly exposed plates has a duration of only two or three minutes.

NOTES ON THE EXPLOSION OF A GAS CYLINDER.

On January 28 a lamentable and fatal accident happened to Mr. Thomas Arthur Bewley by the explosion of a cylinder of compressed gas at the shipbuilding yard of Messrs. Bewley & Webb, East Wall, Dublin. The deceased gentleman established machinery for the compression of gases, and supplied the trade with compressed coal gas and oxygen in wrought-iron cylinders. Owing to the uncertainty of the exact cause of the explosion a good deal of anxiety has been excited amongst the public.

The combustible gas, whether hydrogen or coal gas, was stored in cylinders painted red, and the oxygen in cylinders painted black. This rule was intended to be invariable. On December 27, Mr. Chancellor, of Sackville-street, sent an urgent request for a bottle of oxygen, but there being none of the black cylinders available, owing to the excess of business at Christmas-time, Mr. Chancellor was informed that he could be accommodated with oxygen in a red cylinder. The cylinder was returned on January 15. Afterwards an application was made for a bottle of hydrogen and one of oxygen. It had been forgotten by the deceased that this bottle was charged with oxygen, and, being red, it was simply filled up and sent out as hydrogen.

It was attached to a limelight apparatus, when the discovery was made that it contained mixed gases, for the indiarubber connecting tube was blown off as soon as the gas was ignited at the burner. It was placed on one side and labelled "mixed gases." Two days afterwards the bottle was sent back to Mr. Bewley and was placed on the table in the drawing office, where it remained until the fatal occurrence.

Instead of allowing the gas to blow off he tested a small quantity of the gas in a tube in the presence of one of his foremen, who described the "spurt" with which it went off when a lighted match was applied to the mouth of the tube. The flame seen was a small blue one. He stated to the foreman that as the amount of inflammable gas was so small he intended to use the cylinder himself as an oxygen cylinder. As the pressure was higher than he required, a portion of the gas was allowed to pass into another black cylinder, which reduced its tension from 800 to 400 lbs. (the breaking strain of the bottle is well over 2000 or 2500 lbs.). It must be remarked that the connecting tube did not fit satisfactorily, and that at the time (two o'clock) a small gas jet was burning in the room. At 4.25 the explosion occurred, but as no one had been in the drawing office but Mr. Bewley himself the conditions under which the explosion took place are not precisely known. The evidence, however, is fairly conclusive.

In the first place, it must be stated that the metal of the cylinder was perfectly sound, and in the interior there was no appearance either of oil or of rust. While the upper part of the cylinder was blown to pieces, the body of it struck the arch over a window and caused the wall to bulge; it then ricocheted apparently against the wall, and passed through a window opposite to where it had first struck. The upper end of the cylinder was found at a much greater distance from the building.

One witness, who saw a gauge on the bottle marking 800 lbs., believed that the cylinder had been overcharged, and that disruption occurred simply by the elastic force of the gas. Having examined the premises, I was in a position to state at the inquest that the nature of the explosion was most certainly that of a detonation. The table and drawers were splintered into matchwood, and the glass from the window, as it lay on the ground, presented the peculiarities of fracture which are characteristic of such an explosion.

The examination of the top of the cylinder just below the shoulder showed that the fractured metal at this part had a different appearance from the other fractured surfaces. Instead of being bright it was burnt all the way round, that is to say, covered with magnetic oxide. Moreover, the medical evidence showed that death was caused by shock, and the force of the explosion threw the body out of the room. While the left hand was severed from the arm at four inches above the wrist, the right was charred, and singeing was noticed on the right leg, and the hair was crisp from the same cause.

Without doubt the explosion occurred from the detonation of mixed gases within the cylinder.

The valves of both cylinders, which had been connected by a tube previously, were found wide open. The ignition of the gases was most probably caused, not by any chemical action spontaneously taking place within the cylinder, but either by a leakage, which was tested by applying a match, or, the leakage being serious, the gases were fired by a lighted gas jet. It must be remembered that what was believed to be the same gas had previously exploded in the limelight apparatus, merely blowing off the indiarubber tube, but, the valve being but slightly open, the explosion was not communicated to the interior of the cylinder because the pressure was higher and the issuing gas was travelling at too great a speed for the temperature of ignition to be maintained in the stream issuing from the small orifice in so large a mass of metal.

For the better understanding of this explanation I will refer to a very simple experiment. Carbon monoxide stored in a gas holder under a pressure of six inches of water cannot be burnt from an ordinary gas jet, but if the size of the orifice be enlarged to $\frac{1}{16}$ or $\frac{1}{8}$ of an inch it can be made to burn when the pressure is somewhat reduced. There is no material alteration in the conditions of the experiment if the gas be mixed with air or oxygen. In fact, the temperature of ignition cannot be maintained in contact with the cooling mass which surrounds a small orifice, or with the gas under a very rapid rate of flow.

We cannot precisely ascertain the temperature of ignition or the rapidity of explosion of the mixture of gases contained in the cylinder, but it certainly contained a large excess of oxygen, and the conditions under which it was first found to be dangerous were different and less favourable to explosion than after the pressure was reduced.

The verdict of accidental death was coupled with a recommendation that the public should be protected from similar accidents by a Government stamp being fixed to all cylinders used for such purposes. But greater safety would be secured by making the fittings for hydrogen and oxygen cylinders so entirely different that it would be practically impossible to charge a cylinder with wrong gas.

PATENT COMPLETED.

AN "INSTANTANEOUS" PHOTOGRAPHIC SHUTTER.

No. 16,224. JAMES LYON, Engineering Department, Cambridge University.—*November 9, 1888.*

A PHOTOGRAPHIC shutter for photographing rapidly moving objects.

This shutter opens the lens gradually, it then leaves the lens fully open for a much longer time than was occupied in opening it, and it finally closes the lens gradually in a time nearly the same as that taken to open it.

However short the whole time the lens is wholly or partially uncovered the ratio of the time that the lens is fully open to the time taken in opening and shutting the lens is large.

The object of the shutter is to give the largest possible amount of light to the sensitive plate during any given time of exposure of the plate to light entering the camera through the lens.

The movements of the two leaves which form the covering to the lens are effected by a disc having in it two pins each of which operates a leaf. The pins work in two slots, cut in two sheets of metal called sliders, the slots being so shaped that when the disc revolves the sliders move through a certain distance; the pins then arrive at a portion of the slots which are concentric with the centre of rotation of the disc, and, therefore, the pins move through portions of their paths without moving the sliders; the pins then arrive at portions of the slots which are so shaped that the sliders are moved in the contrary directions.

The movements of the sliders are multiplied in the leaves by means of levers or otherwise. The disc is made to rotate by means of a snitable spring, and the exposure is effected by releasing the disc by means of a catch operated by a pneumatic cylinder or otherwise. The momenta of the working parts are so adjusted as not to shake the camera.

UNDER the title of *The True Position of Patentees*, Mr. H. Moy Thomas has published, through Messrs. Simpkin, Marshall, & Co., a little book in which the patent laws and regulations at home, abroad, and in our Colonies and dependencies are explained for the information of English inventors.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.
On Thursday night, last week, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. C. H. Cooke presided.

Mr. F. W. HART exhibited a view of Weston's Electric Light Factory, taken at half past ten p.m., by the magnesium flash light. He also exhibited a group taken by the flash light at the Freemasons' Tavern by the Stereoscopic Company and himself; he employed fifteen magnesium lamps, which were fired simultaneously; the size of the negative was 12 x 10 and the weight of magnesium burnt sixty or seventy grains.

The CHAIRMAN remarked that the photograph was a very good one, but the magnesium light had acted upon the eyes of some of the sitters.

Mr. A. HADDON said that one "Free Lance" had been criticising him in a photographic journal by separating a portion of his remarks from the context; such action was unjust to public speakers, and people who committed such actions did more harm than good to the photographic community. After stating that "Free Lance's" version was inaccurate, Mr. Haddon continued that that writer had said that an angular ring on the back lens did no harm, but he (Mr. Haddon) asserted that it did do harm, and cut off some rays which would otherwise reach the plate. He was prepared to prove his point or to admit he was wrong if "Free Lance" would on any Saturday come down to Greenwich to experimentally test the matter, but only on condition that the result should be published as widely as the original charge against him. At a previous meeting Mr. Kerr had said that he had ascertained that a quarter of the lens must be uncovered before the whole of the plate is covered by the image, and this went towards supporting his (Mr. Haddon's) assertions. If "Free Lance" accepted the challenge he (Mr. Haddon) would promise not to reveal his identity.

Mr. Hart exhibited some good photographs of interiors taken by the flash light.

Mr. J. B. R. WELLINGTON exhibited his new detective camera, the chief novelty in which is, he said, that it opens from the bottom, the halves of which bottom slide into the ends of the camera when the latter is opened. The camera has a roller blind shutter working close to the front of the plate; he had found it to answer very well. The camera carries six double slides ingeniously packed inside with the maximum economy of space and remain inside while the camera is in use. The whole weighs six and a half pounds without plates.

Mr. J. G. R. WOLLASTON asked if Mr. Hart would give a demonstration with his simultaneously flashing lamps before the Association.

Mr. HART replied that for the present he was short of lamps.

An exhibition of lantern slides then took place. Some pictures by Mr. Wollaston from negatives taken on Eastman's stripping films were projected on the screen. Then followed views by Messrs. Cooke, H. M. Hastings, and J. Joel.

Mr. HASTINGS said that some of his negatives for the slides had been efficiently intensified by means of Mr. Wellington's sulphocyanide developer.

Mr. H. S. STARNES exhibited some lantern views from Kodak camera negatives; also some views of ordinary size on plates containing white silver. He said that he had created one hundred and twenty plates at a cost of five pence halfpenny.

Slides by Mr. Wellington followed, then came those which had been publicly announced for exhibition that evening, namely, some views of Holland, taken by Mr. P. Fincham, and brought by Mr. T. E. Freshwater; also some views of scenes in the same country taken by Mr. F. A. Hartman, who gave an explanatory description.

All these were viewed with much interest, and Mr. FRESHWATER said that Mr. Fincham's negatives were four inches square; the slides were wet collodion transparencies taken from the said negatives.

Mr. FRESHWATER then exhibited some views of the Jubilee procession taken by himself, and stated that at the next lantern meeting he would bring a series of slides illustrating manners and customs in India.

CAMERA CLUB.

On Thursday evening, February 14, lantern slides were shown at the Camera Club, a large and varied collection having been brought together. The subjects exhibited were as follows:—Tintern Abbey series and microscopic slides, Mr. F. Evans; hand camera work, Mr. Beck and Mr. Shipton; landscape, Mr. B. G. Wilkinson, jun.; scenery at home and in Canada, Lieutenant Gladstone; views around Richmond, Mr. J. H. Williams; slides on ferrotype and on gelatine-albumen plates, Mr. H. M. Elder; also work by Messrs. Ferrero, Laurie, Barclay, Mackell, Major Scott, and the Hon. A. W. Erskine.

Some transparencies from negatives by Mr. Gambier Bolton were lent by Messrs. Fry & Co., and, at the request of members present, the American slides received in the 1884-5 exchange were again shown.

During the evening Mr. ROBERTS drew attention to the new form of Beard & Oskey's regulator, which was in use at the lantern, and Mr. Ferrero exhibited a new dark-room lamp introduced by Messrs. Marion & Co.

The subject on Thursday, February 23, will be *Notes on Photographic Lenses*, when a paper will be read by Rev. T. Perkins, M.A.

NORTH SURREY PHOTOGRAPHIC SOCIETY.

A MEETING of the above Society was held at the West Norwood Club on Tuesday evening, February 12. The chair was occupied by Mr. W. H. Walker. Messrs. W. Rice and H. S. Bellsmith were elected members of the Society, and Mr. W. Gale was elected an honorary member.

A demonstration of the working of the Eastman Company's new stripping films, their transferotype and bromide papers, was given by Mr. Bellsmith.

Mr. BELLSMITH announced that in their new film the Company had entirely overcome the earlier difficulties which had been encountered by those gentlemen who had adopted their use—viz., damp spots and difficulty in stripping.

The next meeting of the Society will be on February 26, when Mr. Wolf will occupy the chair.

SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE monthly meeting of the Society was held on Tuesday, February 5.—Mr. H. J. Taylor occupied the chair.

Three new members were elected.

The annual lantern slide competition for the best series of six slides made from negatives taken during the previous year was held. Five competitors entered. The slides were exhibited. The first award fell to Mr. Furniss, and Mr. E. Beck took the second.

A discussion regarding the merits and demerits of the slides took place, and it was considered that the best slide was one in the set shown by Mr. Hunt.

A *Concours* was held by the above Society, on the 12th instant, and was well attended.

A large number of photographs, the work of the members, and including the various prize and competition pictures of the past season, were exhibited on the walls of the Hall.

A loan collection of photographs included examples by Messrs. H. P. Robinson, J. Gale, Bedford, Lemere & Co., F. M. Sutcliffe, Morgan & Kidd.

Photographic appliances were exhibited by Messrs. Culley & Preston, including a portable developing tent, shutters, and cameras. Messrs. Hibbert Brothers also showed cameras, stands, &c., including one of Messrs. W. Watson & Sons' new patent cameras.

Mr. Bromley had some fine stereoscopic transparencies and prints, also a microscope showing micro-photographs.

During the evening a large number of views, taken by the members, of places of interest in Sheffield and neighbourhood, were shown by Mr. W. D. Forsdike's lantern.

BRIGHTON PHOTOGRAPHIC SOCIETY.

A MEETING of this newly-formed Society was held at 35, Vernon-terrace, on Thursday, the 14th instant. Mr. D. E. Caust was voted to the chair.

The minutes of the last meeting having been confirmed, the officers for the year were elected, viz.:—*President*: Dr. W. H. Rean.—*Vice-President*: Mr. W. Jago, F.R.S.—*Committee*: Messrs. Foxall, Court, Harncastle, Burt, Sharp, G. Perren, Wall, R. Wicks, E. J. Bedford, and Devereux.—*Treasurer*: Mr. J. P. Silsbury Roberts.—*Secretary*: Mr. A. H. C. Corler.

A discussion then ensued as to the room to be used by the Society, and eventually the matter was referred to the Committee to report on at the next meeting.

The meetings of the Society will be held, during the winter months, on the second and fourth Tuesdays in each month, at a quarter past eight p.m. The Society is open to photographers, amateur and professional, either ladies or gentlemen. All applications for membership, &c., to be sent to the Hon. Secretary, Mr. A. H. C. Corler, 42, Montpelier-road, Brighton.

DERBY PHOTOGRAPHIC SOCIETY.

THE members of this Society held their usual monthly meeting in their new rooms, Derwent-buildings, 3, Derwent-street, on Tuesday, February 12.—Mr. R. Keene presiding.

Mr. T. A. SCOTTON read a paper and gave a demonstration on *Lantern Slide Making*. He also gave a demonstration on making transferotypes on opal.

The lantern demonstration was supplemented by an exhibition of lantern slides by Mr. E. J. Lovejoy (Hon. Secretary).

The members of this Society have now taken rooms of their own, and intend, as soon as possible, to fit up a dark room. They have a fairly good library.

MANCHESTER PHOTOGRAPHIC SOCIETY.

A MEETING was held on February 14.—Mr. John Schofield, Vice-President, in the chair.

Messrs. James Whittaker and W. Schofield were elected members.

The evening was open for short communications.

Mr. C. F. BURNAN had been trying hydroquinone for stereoscopic transparencies. He was rather in favour of it for some classes of work, but thought it was apt to produce shadows too clear, and high lights too dense, for negatives; in fact, with his present experience, he would be rather afraid to develop a negative on which he set much store. Other opinions were given in favour of hydroquinone and against it.

Mr. G. H. JOYNSON had been working the wet collodion process for microscopic work, and failed to produce the fine image he desired with iron developers, even when it contained gelatine or albumen, as had been advocated by Mr. J. Pollitt.

Mr. ABEL HEYWOOD, jun., said Dancer, of Manchester, used to produce some of the finest work of that class, and Miss Dancer was at present engaged in this branch of photography. He advised Mr. Johnson to call and see the lady named.

Mr. ATHERTON thought a slow and very much restrained developer would be the best.

Mr. F. EDWARDS said Messrs. Mawson & Swan gave special instructions and sold special collodion for this class of work. He believed they advised a weak developer.

Mr. JOHN S. POLLITT considered the great secret in obtaining a fine deposit was in slow development, accompanied by the addition of gelatine and iron; but pyrogallol acid he believed to be the best of all. The latter was slower to the extent of about fifty per cent. than iron. Long exposures and slow development produced fine grain, and vice versa. He called attention to the sixth edition of Harwich's *Photographic Chemistry*, pp. 36 to 43, and also to the ninth edition, pp. 124 to 132, wherein were stated some curious experiments made by the late J. W. Young, a highly respected member of this Society, viz., that it was possible to fix a collodio-albumen plate and afterwards to develop it. He (Mr. Pollitt) had tried several times to repeat this experiment, but had failed.

Mr. AHERTON remembered the circumstances very well, and he had often done it. The image was, however, weaker than if developed first and then fixed.

The Hon. SECRETARY (Mr. W. I. Chadwick) said the result of Mr. Young's success might, no doubt, be from the fact that the collodio-albumen plates were finally dipped in gallic acid before drying, which was to a certain extent a developing agent.

Mr. JOHN SCHOFIELD called attention to a difficulty he had experienced in toning ordinary silver prints which had been washed in hard water. The same paper when washed in soft water toned quite readily.

The Hon. SECRETARY said he should have expected the conditions to be reversed. Ready sensitised paper was generally very acid, and when this is so the prints should be washed in two changes of water, and then the third water should be made alkaline with carbonate of soda, after which there was very little trouble in toning.

Mr. BRENNAN referred to the Dublin explosion. He thought the matter was too serious to pass by in this Society unobserved. He was telling his little boy about the explosion, and the boy asked why the cylinder then in his room did not "go off." "Really," said Mr. Brennan, "I could not tell him why it did not."

Mr. HEYWOOD, jun., said the matter was so serious he would never have a cylinder about his home again.

Mr. W. J. CUNLIFFE and others were of the opinion that unless some assurance were given to the public, it should not be sold to inexperienced persons.

The Hon. SECRETARY had seen the report of the inquiry into the cause of the explosion, and expressed his views for precautions in future (as published in the last issue of *The British Journal of Photography*), the idea of having different sized screw ends to the oxygen and hydrogen cylinders being highly approved of by all, and the only satisfactory way in which public confidence could be restored.

Mr. J. T. LEES said the purity of the gases could be easily tested by filling a soda-water bottle with water, then holding it neck downwards in a bucket of water, and allowing the gas from one cylinder to bubble in or fill the glass bottle, then applying a lighted taper. If pure hydrogen were present, the gas would burn at the neck of the bottle; if oxygen, the taper would burn brighter. If mixed gases, they would explode, and the explosion would be a small affair and do no damage.

Mr. H. WHITEFIELD thought the test might be a very good one, but what was a lanternist to do when he found he had got either two cylinders of oxygen or two of hydrogen, or a mixed cylinder? What we required was some plan by which the gases could not get mixed, and the suggestion of Mr. Chadwick was the only one that met the case.

Mr. HEYWOOD, jun., thought the suggestion of Mr. Lees a very good one, and worthy of everybody's consideration.

But again the members were almost unanimous in requesting some better system than at present exists, and ultimately it was resolved that a committee, consisting of Messrs. Abel Heywood, jun., C. F. Brennan, John Schofield, and the Hon. Secretary, write to the President (Sir Henry Roscoe, M.P.) on the subject, and report at the next meeting.

Mr. H. SMITH exhibited a very nice print by Willis's cold-bath platinotype process. After many trials with various other papers he considered this the best; it was much quicker than silver printing.

Mr. J. WITHAM gave his experiences with Pizzighelli platinotype paper. He considered it very reliable, but, in reply to a question from the Hon. Secretary, said his experience was based upon only one sheet.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

The ordinary meeting of the above was held in the Society's Rooms, Grand Hotel, Colmore-row, on Thursday, the 14th instant.—Mr. W. J. Harrison, F.G.S., in the chair.

Messrs. W. F. May, T. H. Kendrick, and G. E. Wilson, were elected members.

Mr. W. THOMAS HORTON then delivered his paper on *Daguerreotype*, giving full particulars of this now extinct practice of photography, and exhibited the apparatus used in the process, with a number of *Daguerreotypes*.

In the discussion which followed, in answer to the question, "What kind of lens was used in *Daguerreotype*?" Mr. J. EDMONDS said an ordinary single lens was used, but allowance had to be made for focussing. Early lenses were limited in variety, but good views were taken about that time on calotype paper with a non-achromatic meniscus lens. He remembered excellent portrait lenses by Voigtlander in which the chemical and actinic foci did not coincide, and which required the dark slide and the focussing screen of the camera to be set at a different distance from the lens, in order that the plate might be in the true chemical focus. Mr. Edmonds referred to his recollections of photography when Mr. Whitlock practised *Daguerreotype* under "Beard's patent," and exhibited photographs of Birmingham celebrities at his shop in that part of New-street which is now Stephenson-place, also of Mr. James Johnstone, a skilful photographer, who practised *Daguerreotype* at that early date.

Mr. J. COTTEWILL: Members had spoken as though the difference between the chemical and visual foci was a novelty nowadays, but at the present time he found it still prevalent in many cases in modern lenses. Out of six portrait and landscape lenses in his possession only one is perfectly coincident in chemical and visual focus.

Mr. G. M. LIFF had some time ago an old camera with single lens of early make, which, after focussing on the glass, required the back to be moved to obtain the correct focussing for the plate.

Mr. W. J. HARRISON: The lenses used by Daguerre and others in the early days of photography were uncorrected in this respect, that the chemical and visual foci were not coincident. This was pointed out by Towson, of Liverpool, about 1840, and was remedied by the genius of the Viennese professor Petzval. The speaker exhibited a large picture of Daguerre (a fine print by Nair, of Paris, on Eastman paper), being a copy of a *Daguerreotype* taken about 1840.

Mr. E. C. MIDDLETON had seen old cameras with one opening for focussing screen and another for dark slide.

Mr. WALTER GRIFFITHS then read the following paperette on *His Experience with "Kristaline" as applied to Photography*—

I expect all of you have heard of kristaline, but, perhaps, few of you have tried it. It is an American production, as the spelling of it with a "K" would reveal. It is, I believe, manufactured as a lacquer for brass and other goods, but it also has some properties as a photographic varnish that are useful and, therefore, interesting to us. Of its composition I am quite ignorant; perhaps some of the members can enlighten me; but it differs greatly from the negative varnishes that we are accustomed to, or lacquers either. It smells strongly of "pear drops," and, oddly enough, inhaling the vapour induces coughing; at least, it does to me. Unlike varnish, it is very thick, and runs almost like treacle, which at first gives the impression it is too thick and wasteful; however, a large part of it drains off again, and the remaining film is found to be about right in thickness. A plate coated with it takes half an hour to dry cold, and it never seems to be tacky like ordinary varnish. It does not mess your fingers. With heat it dries in a minute or so, but not so quickly as ordinary varnish. It will not mix with water, but on bringing it in contact with it it does not form a white cloud or precipitate that some varnishes do, particularly common ones. It will not mix with alcohol properly, but will mix with ether, with which it may be thinned, but on coating a plate the ether soon evaporates and leaves the kristaline as slow drying as ever. As regards the nature of the film, I find it not so impervious to water or moisture as I had understood. A gelatine film will soon swell under it; however, for all that, it compares favourably with ordinary varnish for all practical printing purposes, and, in fact, has some advantages. I have not had any silver stains upon it from albumen paper printing, but am not prepared to say it is proof against that. I think one of its most valuable features is that a film of it assimilates itself closely to the character of the surface upon which it is spread; that is to say, a dead or matt surface remains almost as dead or matt underneath it, which cannot be said of ordinary varnish. It is, therefore, peculiarly suited for such things as opal pictures, either bromide or carbon. A film upon plain glass dries so much like the glass itself that it is difficult to distinguish which side it is upon, the more so because it is perfectly free from waves and all surface markings whatever; in this respect it has the advantage over most varnishes. It is quite possible that a coat of it on the back of a silver print would materially lengthen its life; and, by the way, it is useful to paint your bottle labels with, keeps them clean and fast to the bottles for a long time, and can be applied with a brush. As regards what usage it will stand, dusting has no effect upon it, but I should be afraid to indulge in washing it. Sponging it with water soon abrades the surface, and if continued the entire film crumbles off. I am speaking now of it on a gelatine negative. Sulphuric acid does not really remove it, but rather seems to combine with it (which may throw a little side light upon its composition); but it rapidly penetrates it and eats away the bromide image underneath. Neither nitric nor hydrochloric acids have any apparent effect upon it. And now as to its defects. Beyond some trivial inconveniences I confess I do not know of any that are not possessed by other varnishes, but as a retoucher I should expect it to be equal in that respect, as it retains the dull surface of the gelatine. I consider all our varnishes are defective in one particular quality, and that is they are not absorbed by the gelatine film. Kristaline is no exception to the rule. A collodion picture has the advantage of its gelatine rival in this respect, for the varnish and the collodion film having similar solvents, they partially combine, the latter becoming permeated with the varnish, and so able to withstand as much as the varnish will. If you were to employ a varnish with pure solvents it would actually dissolve the collodion picture, or, rather, the collodion in which the picture is imbedded; now, gelatine is not so protected; silver stains can get through even varnish to the gelatine, and if they do, "woe betide" the negative, for it is more difficult to get them out again than if it had not been varnished at all. A varnish, to be perfect, should be absorbed by the gelatine film. I am at present only acquainted with one receipt—"White lac dissolved in boiling water, with the aid of borax," and applied to the plate while the latter is wet.

A short discussion followed.

The CHAIRMAN announced that at the next meeting, on the 24th instant, Mr. J. F. Hall Edwards will read a paper on *Photo-micrography*.

LEICESTER AND LEICESTERSHIRE PHOTOGRAPHIC SOCIETY.

At the meeting of this Society, on February 12, Mr. S. S. Partridge, Vice-President, in the absence of the President, occupied the chair.

The members proceeded with the competition for lantern slides arranged for this evening, forty-eight slides being projected on the screen. The whole of the slides were of exceptional merit, leaving little to be desired, and presenting some difficulty in awarding the prizes. The slides for competition were sent in by Messrs. W. T. Tucker, S. S. Partridge, Squire Wilson, W. Taylor, Perritt, Weatherhead, and J. T. Cook. In the final voting Mr. W. T. Tucker was awarded the silver medal of the Society for six slides, which did him ample justice; and the bronze medal was awarded to Mr. W. Taylor for six slides.

It was announced that Mr. J. T. Cook, a member of the Society, had consented to deliver a lecture in connexion with the Society on Thursday, March 28, in the Lecture Room, Temperance Hall, entitled *Through Australia and New Zealand*, illustrated with lantern slides.

The meeting was then adjourned until March 13, on which date the print competition for the Society's silver and bronze medals will take place.

BIRKENHEAD PHOTOGRAPHIC ASSOCIATION.

The ordinary meeting of the above was held in the Hamilton Rooms, Price-street, on Thursday evening, February 14, 1889.—The President (Mr. Paul Lange) in the chair.

Messrs. E. Twigg, G. M. Noakes, William Tomkinson, William Faltin, Francis Faltin, W. A. Brown, Walter Geikie, and John Wynne, were elected as members.

The PRESIDENT, after welcoming the members to the new rooms, said that he had a very painful duty to perform by drawing the attention of the members to the sudden death of Mr. W. F. Riley, a member of the Council, an ardent worker in photography, and an ever-willing helper to beginners; he also stated that the Secretary had forwarded a letter of condolence to the widow, Mrs. Riley.

The medals which had been awarded in the competitions for 1888 were then distributed to the winners—Messrs. Lange, Mackrell, Evans, Cornish, and Wilkinson.

The PRESIDENT read a letter from Mr. H. N. Atkins, in which he stated that, owing to leaving the city he was obliged to tender his resignation; it was, therefore, unanimously resolved by the members that Mr. Atkins be elected an honorary member of the Association.

The competition, "Bromide paper *versus* Platinotype," by Messrs. H. Wilkinson and Paul Lange, was then voted on by the members, the majority being in favour of the platinum print. Both competitors used the same negative.

Mr. W. B. Beaton exhibited a very ingenious detective camera, which found great favour amongst the members.

The remainder of the evening having been set apart for a lantern exhibition of slides, some two hundred slides by members were shown on the screen, the average quality of which was very excellent, giving much pleasure to the members and friends present.

IPSWICH PHOTOGRAPHIC SOCIETY.

THE monthly meeting of the above Society was held on Tuesday evening, the 12th instant.—Mr. J. Dixon Piper in the chair.

The main business of the evening was a demonstration of enlarging, given by Mr. A. C. Churchman. By means of one of Lancaster's enlarging lanterns Mr. Churchman exposed and then developed several enlargements from quarter-plate negatives on to 10 x 8 bromide paper, and turned out good pictures.

Two new members (Messrs. Fiske and H. P. Evans) were elected.

Mr. J. C. Wiggin exhibited Ashford's patent tripod and several wax paper negatives taken by his late father.

NOTTINGHAMSHIRE AMATEUR PHOTOGRAPHIC ASSOCIATION.

AT the fortnightly meeting on the 18th instant, Mr. Henry Hlanly, L.D.S. Edin., President, occupied the chair.

The following gentlemen were elected members:—The Rev. A. C. Beckton, Messrs. P. Peach, and J. G. Westby.

The PRESIDENT then called on Mr. T. W. Cave, M.R.C.V.S., F.R.M.S., and Mr. W. H. Pratt, F.R.M.S., for their lecture on *Photo-micrography*.

Mr. CAVE said: Before introducing the subject of photo-micrography it is my wish to point out that the paper is the joint work of Mr. Pratt and myself. The paper is merely a description of our apparatus and the way in which we are accustomed to work. The apparatus has been designed by ourselves, and is the outcome of practical experience during three or four years' work in this subject. As to the method in which we work, there are probably other methods much superior to ours, but in our paper this evening we have endeavoured to give you the results of our own experiences, pointing out the difficulties and failures, and exhibiting on the screen a few lantern slides which we believe to be fairly good examples of successful photo-micrography. The lecturer then gave a full description of the apparatus used, pointing out and explaining the working of the different parts. Concerning the light, they themselves use a Welshbach incandescent burner. The arrangement of the object and the exposure of the plate were explained. Slides were then thrown upon the screen, including prolocata of blowfly, fore-leg of water beetle, gizzard of cricket, &c. In conclusion, he hoped that they had succeeded in interesting them in a branch of the great art of photography which is valuable to the cause of science and valuable as a most fascinating study, which can be carried on when other branches of the art must be laid aside owing to the want of sufficient light.

SOUTHPORT PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held in the Young Men's Christian Association Rooms on Monday evening, February 11.—Mr. R. Wyles (the President) in the chair.

Mr. P. GRAHAM, of Derby, gave a demonstration entitled *The Relation between Exposure and Development*.

The experiments were directed chiefly to showing the immense latitude in the exposure possible with development suited to the occasion. Mr. Graham having made a special study of this point, the plates employed were the new series issued by the Ilford Company, in which a special modification with a view to this latitude is embodied. The plates were not brought by the operator for the purpose, but taken from the stock of Mr. Wyles. After ascertaining the normal exposures required by a quick plate of the first reputation, and that being found ten seconds, exposures were given of one-third, one-half, and up to six times the normal ten seconds, the whole being made to yield good results, with little trace of either under or over timing. Another experiment was a test for balance. A sitter was seated in a strong blaze of light, clad in white on the lighted side and dark velvet on the shadow side, and exposures given of three and sixty seconds. The negatives were equally good, and both perfectly free of any balance. Further experiments with landscape exposures were shown, confirming the fact of the extraordinary latitude claimed.

The PRESIDENT, summing up the results shown, thought that Mr. Graham had made good his claim to the possibility of getting good results with widely diverging exposures, and had shown the members the necessity for studying conditions; and that in their own hands, by modifying development to suit exposure, much more could be done than was generally supposed possible.

Mr. BOOTHROYD and Mr. MARSDEN (the Hon. Secretary) followed, enforcing the same principle, and moving the thanks of the Society for his interesting demonstrations.

The chief principles advocated were understood to be as follows:—The use of an invariable quantity of alkali, quantity being adjusted to the constitution of the plate used and adhered to constantly. Dry pyro in preference to any solutions, quantity varied to suit the density required. In studio work, concentrated lighting requires less pyro, and lighting approaching a flat or all-round character, more pyro. Sulphite usable with the fixed alkalies, not with ammonia, to produce the colour preferred. Enough may be used to render the steam clearing solution unnecessary. Bromide used at the start when over timing is suspected, afterwards as may be indicated.

BRECHIN PHOTOGRAPHIC ASSOCIATION.

THIS Association held a lantern evening on Friday, the 1st instant,—Dr. Anderson in the chair.

About one hundred friends were present, and upwards of two hundred slides belonging to various members were passed through the lantern.

Mr. A. R. McLEAN MURRAY, on behalf of the strangers, tendered thanks to the Association for the pleasant evening they had spent.

THE ordinary monthly meeting was held on Wednesday evening, the 13th instant.—Mr. R. A. Scott, M.A., Chairman.

Mr. Duncan, Edzell, and Mr. Davidson, Montrose, were elected members; and thereafter Mr. J. D. Ross read a paper on *Lantern Slide Making*. He strongly recommended hydroquinone as the developer for transparencies, and, after seeing samples of slides made with different developers, most of the members agreed with him. Two slides were developed successfully.

A lively discussion followed.

AMATEUR PHOTOGRAPHIC SOCIETY OF MADRAS.

THE first annual meeting of the above Society was held on January 15, Mr. F. B. Hanna, M.A., President, in the chair, H. E. Lord Connemara being present with Viscount Marsham, A.D.C.

The members present unanimously elected His Excellency a member of the Society, and Lord Connemara consented to allow his name to be placed on the list as one of the patrons of the Society, H. E. Sir Charles Arbuthnot, K.C.B., R.A., the Commander-in-Chief of the Madras Army, already occupying that position from the commencement.

The report of the Committee was read, showing that the Society was in a very flourishing condition.

The next business was the election of the Committee for the coming year. Mr. F. B. Hanna was elected President, being proposed by Lord Connemara and seconded by Mr. Sundaram Sastri. Messrs. J. C. Hannington, C.S., and C. Mitchie Smith were re-elected Vice-Presidents, the proposition being made by His Excellency and seconded by Mr. T. M. Horsfall. Lord Connemara then proposed that the following gentlemen be elected on the Committee, and this being seconded by the Zemindar of Challypally, was carried:—Colonel A. Curtois, Mr. T. M. Horsfall, Dr. G. Oppert, Mr. W. G. Pavey, Mr. C. Sundaram Sastri, and Captain R. H. C. Tufnell. Mr. Hanna proposed, and Mr. Horsfall seconded, that Mr. Dunsterville be re-elected Secretary and Treasurer, which was carried.

The PRESIDENT then spoke as follows:—It is always a pleasure to a Chairman at an annual meeting to be able to say that the year, the proceedings of which he was about to review, had been a successful one. He thought there could be no doubt that this had been the case with their Society. Their members were recruited from a limited portion of the community, yet, in the first year of the Society, fifty-one members had joined, one of these had died, and one resigned, so that at the end of the year the number of members was forty-nine. Meetings had been regularly held on the last Tuesday in each month, and at these meetings a number of pictures, the subject of which was in each case fixed at the previous meeting, had been exhibited. This method insured new pictures and was specially intended to encourage the less experienced members of the Society, who would, he hoped, avail themselves fully of the opportunity thus afforded of showing their work and of hearing the opinions expressed by more experienced photographers. Mention has been made in the report of the exhibitions of lantern slides that had been given at his house; as this had been so much appreciated, he hoped to have the pleasure of giving similar exhibitions during the current year. The pictures sent in for the recent competition were very good, but he regretted there were so few competitors; he hoped, however, that on the next occasion more members would send in pictures. He trusted that the members of the Society were fully satisfied with the work of the Committee during the past year—by far the greatest part of the credit was due to Mr. Dunsterville, their Hon. Secretary, on whom devolved all the hard work; but Mr. Dunsterville was one of those happily constituted men who were never so happy as when they are working hard; this, combined with a great love of order and regularity, enabled him to get through a wonderful amount of work, and accounted for the flourishing condition financially, and otherwise, of the Societies in which he took a special interest.

H. E. Lord CONNEMARA then congratulated the Society on having had such a successful beginning, and expressed a hope that the coming year would show even better results. He further said that he would like to see a photographic exhibition held in Madras, and trusted the Committee would see their way to carry out the idea.

Correspondence.

Correspondents should never write on both sides of the paper.

STRIPPING FILMS.

To the Editor.

SIR,—While paying due credit to Vergara and to Fry for their attempts to produce satisfactory films, it must be admitted that there appears, to outsiders at least, a regrettable want of enterprise in following the American lead in the direction of stripping films and roller spools. Why should this be? and why should our British emulsion makers, who originally led the van, quietly allow themselves to be hopelessly distanced by Eastman or by Carbutt?

There is no doubt that "films" are the ideal of the future, both for the studio and for the field. Rent, storage room, and weight will be saved in the studio by using strippers instead of plates. Then, also, the greater facilities for reversing negatives and for retouching from both sides, are all in favour of the film. So, too, is the diminished risk of

halation from large surfaces of white dress or skin in portraiture. For landscape work, when either great distances or weight are in question, the film, or the paper-coated roller, present overwhelming advantages.

Clearly, then, "films" have all the future before them, and the total disappearance of glass as a support is a mere matter of time. I write to ask your support to urge emulsion makers to show some enterprise in banishing glass as a support for studio work, and in adopting roller spools for the field. Glass, we all know, is heavy, easily broken, and favours halation. Why should not all manufacturers adopt some other support for plate films (or cut films), such as vulcanite, ebonite, celluloid, or stiffened cardboard? Emulsion could then be coated on a soluble substratum of gelatine, all plates could be stripped, and the supports returned to the manufacturer and credited for. Halation, too, would be greatly diminished by a dark-coloured support, which would practically amount to a ready-made "backing." In rapidity, too, the emulsion would be slightly increased, as compared to glass (as seems the case with paper backing), owing to absence of refraction.

Demand would soon cause a great reduction in price of such supports as vulcanite or ebonite, whilst any temporary excess of cost would be compensated for by decrease of weight (bulk for bulk), diminished risk of breakage, and allowances for returns.

I trust soon to hear that the winter has been turned to good account by some of the large emulsion firms in the direction of coated bands of paper for roller slides. Capital is not wanting here just now, and it seems scarcely creditable to the profession that we should have to rely on foreign makers for roller spools.—I am, yours, &c.,
PATRIOT.

WEIGHTS AND MEASURES.

To the Editor.

SIR,—Owing to the great inconvenience of readily ascertaining the proportional quantities contained in the numerous formulæ with which photographers have to deal, the Photographic Club has taken the matter in hand, and formed a Committee to devise, if possible, some scheme of weights and measures that will commend itself to photographers generally and supersede the intricate jumble at present existing, and also take means to secure the adoption of such scheme when a definite course has been decided upon.—I am, yours, &c.,
E. DUNMORE, Hon. Secretary.

NORWAY.

To the Editor.

SIR,—Having spent two summers in Norway with a $7\frac{1}{2} \times 5$ and a 12×10 camera, using both plates and films, travelling by land and water, I should strongly advise all intending visitors not to lose sight of their *impedimenta*. The Norwegians are the pleasantest, jolliest, most honest folk under the sun, but they are born without any sense of time. Hurry is unknown, and the laggard is vastly preferred to the tourist who is ever hurrying forward. I know something of the stolidity of Brittany peasants and of the phlegm of Dutch Walloons, but I was hardly prepared for the slow-bloodedness of the Norwegians. Hurry is hateful to them, and to attempt to use the word *Strak* ("Be quick") is certain to change smiles into scowls, and a good reception into indifference or worse. The only way to ensure keeping time is to rise early, and an hour in advance at least, see that horses, guide, boat, or whatever conveyance is required is being prepared and is well in hand. If one waits till close on the stipulated hour, one will find nothing done and be calmly told—"Oh, there is plenty of time yet!" Such was my experience in South, Central, and Northern Norway (with the single exception of one place, where the guide had been in America and knew that time was money).

This characteristic makes it dangerous to send luggage ahead or leave it to follow after. Goodness alone knows when it may turn up. But this peculiarity has with its drawbacks also its advantages. Guides and cariole drivers develop quite a weakness for the ambling photographer. Not only do they enjoy immensely being placed as a figure in a landscape, but they also appropriate the opportunity of studying the whole operation of unpacking, mounting, focussing, and taking a "photo." They thoroughly enter into the enjoyment of an unconscious journey in a dark slide and plate box to England, and, doubtless, vividly picture to themselves British curiosity as keenly exercised with their portraits, as ours is with their splendid scenery. But where their lack of speed comes in usefully to the photographer is, that no one—guides, drivers, boatmen, or even the steamboat folk—objects to—on the contrary, they positively favour—the delays incidental to photography. The guide is glad to get a 12×10 camera and slides off his back as often as you like, and when one goes a rough trip, such as most of those to the great waterfalls or glaciers are, his satisfaction is not to be wondered at. Never in my life have I strained and perspired as up and down Norwegian mountains, and over the rough rock and log-blocked tracks which do duty for paths off the main roads, which are few and far between. Cariole drivers, or the boys or pigs who sit behind them, are delighted that you should stop their spirited ponies with a "pr" or "purr" as often as you list, for each halt rests the hard-worked, willing brutes, who turn every second to good account by nibbling the grass and flowers,

My advice, however, to photographers who visit Norway is to keep to the steamers, and to drive as little as possible.—I am, yours, &c.,
February 16, 1889.
KENRIC B. MURRAY.

RE BRIGHTON PHOTOGRAPHIC SOCIETY.

To the Editor.

SIR,—As a professional member of the above Society I cannot let Mr. Henderson's letter of last week pass without a reply.

I have yet to learn that a few friends cannot come together and form a Society (of course proceeding at once to formulate code of rules, elect officers, &c., as their preliminary work) without laying themselves open to the charges of unfairness that have been made.

The history of this Society is as follows:—On January 22 a meeting was held, at which it was resolved to form a Society. It was formed that evening, about twenty joining. At this meeting a provisional committee was appointed to draft a code of rules, &c.; after this was done the meeting of January 22 was adjourned to February 7. Until we had proceeded thus far we did not even know that Mr. Henderson was in Brighton, much less that he was himself attempting to form a Society. On this coming to our knowledge we at once communicated with him, fully explaining all that had been done; he at once heartily joined with us.

If then Mr. Henderson went round to any friends of his and told them that the Society had *not* been formed, but that they could with himself help to form one, he can only blame himself, and *not* the Society, for any misunderstanding that may have arisen between himself and any of those gentlemen, for our position as a Society was most fully explained to him. This being so, it appears to me that he had no just ground for his action at our meeting of February 7, or for his letter of last Friday.

The whole of this most regrettable misunderstanding has arisen from Mr. Henderson not recognising the fact that the Society *had* been formed, and so could act in any way it thought expedient. We could hardly, because Mr. Henderson and some friends of his wished to join us, begin all our work over again. Are we to start the Society afresh for every batch of new members?—I am, yours, &c.,
GEORGE FOXALL.

To the Editor.

SIR,—Mr. Henderson's letter, re Brighton Photographic Society, contains certain inaccuracies which, with your permission, I should like to correct, as they are calculated to mislead your readers and thus create a prejudice against the Society.

Mr. Henderson states that he called upon me and "heard partly what had been done." This is incorrect. I entered into the matter fully, and told Mr. Henderson, among other things, that a Society had been formed called the Brighton Photographic Society, that the members had appointed a committee to draw up rules, &c., to be discussed and passed at a meeting to be held on February 7. I explained to him the work already done by that committee, and finally intimated that as Mr. Henderson was likely to be of use to the Society I felt sure the members would be glad to welcome him as an original member without election, and upon my own responsibility invited him to be present on the 7th.

This may have been partial information, but it appears to me to have been pretty full. I find it difficult to reconcile these facts with Mr. Henderson's statement, that "his idea was that no regular Society had existed previous to the meeting which took place on the 7th."

Again, I cannot see in any way how the Society is to be held responsible for Mr. Henderson's action in inviting gentlemen to be present at a meeting, when he himself confesses, to quote his own words, that Mr. Rean said "they were not elected," and I may be allowed to state that I subsequently wrote him to the same effect. If gentlemen should feel aggrieved that they did not receive a notice of the meeting on the 7th, surely they must blame Mr. Henderson for inviting them without authority to do so, and not the Society.

The form of "application for membership," which Mr. Henderson states he enclosed to you, in no way assists his case. The footnote, desiring that the form should be returned to me prior to February 7, was in accordance with the letter which I sent to the photographic journals, and which intimated that gentlemen forwarding their applications before that date would, upon election, be admitted without the payment of an entrance-fee.

With the latter portion of Mr. Henderson's letter I have nothing to do. Trusting that I am not taking up too much of your valuable space.—I am, yours, &c.,
W. H. REAN.

36, Vernon-terrace, Brighton, February 16, 1889.

GUTTENBERG'S LAMP.

To the Editor.

SIR,—Kindly allow me a little of your valuable space to reply to "Junius's" remarks regarding my lamp in last week's JOURNAL. "Junius" having chosen to air his views about an apparatus concerning which he had formed a wrong conception, now when in justice to myself I correct

his erroneous criticism, falls back upon a "woman's reason" for sticking to his opinion. Therefore I think there is little further need of refutation on my part; but I would like to add that the mere fact of his designating my lamp a "flash lamp," when the specifications particularly dwell upon its not being such, shows how little "Junius" understood that which he criticised.—I am, yours, &c.,
W. GUTTENBERG.

THE FATAL EXPLOSION OF A GAS CYLINDER AT DUBLIN.

To the Editor.

SIR,—The recommendation to make the couplings of different sizes would not prevent the man in charge of the compressing pumps from accidentally charging the oxygen compressor with coal gas, or *vice versa*, and then refilling a returned half-empty bottle with the wrong gas.

What the public require is perfect security, even if the gases have been accidentally supplied mixed.

Bearing in mind that the most energetic combustion is at once arrested by contact with a sufficient quantity of cold metal, I believe that an explosion would be rendered impossible by attaching a spiral worm of fine copper tubing to the lower portion of the valve, so as to project into the bottle, through which worm the gas would have to pass before reaching the jet. If one coil was found insufficient, two, or even three, coils could be used, one within the other, without materially reducing the capacity of even the smallest-sized bottle.

A Hemmings' safety jet permanently fixed behind the valve and in the bottle would, of course, have the same effect, but would, I think, reduce the pressure too considerably to admit of the use of a mixed gas jet.—I am, yours, &c.,
CLEMENT T. LEAPER.

Technical Schools, Kevin-street, Dublin.

COMPRESSED GAS IN CYLINDERS.

To the Editor.

SIR,—Following on the subject of the article by Mr. G. H. Baker, in your issue of February 13, with reference to the deplorable accident at Dublin, due to the explosion of a gas cylinder, I should like to crave leave to occupy a little of your valuable space with one or two remarks on the use and safety of compressed gas. First, let me say that it would be very much to be regretted if the public mind is permitted to be unduly alarmed, or the confidence of users of compressed gases to be shaken, by this or any other similar calamity.

What is required is not limitation of use, but proper precautions in use, and the diffusion of proper knowledge and the establishment of an efficient system of testing. Nothing more convenient or satisfactory in the way of artificial light for general optical purposes has yet been designed than the limelight as produced by compressed gases, used from separate steel cylinders with a good mixed jet, and the use of such pressure reducers as Beards' new small valve. I speak on this subject with the acquaintance derived from extensive experience in lecturing, and in the physical laboratory. The electric arc light, even where available, is difficult to manage, and incandescent lighting cannot yet, in general optical work, replace the limelight. Hence the steel cylinders are a great boon. Now the risks in their use are obviously,—

First, the metal cylinder may burst, even if filled simply with one gas. This is not a very likely thing to happen. If the cylinder stands the pressure in charging there is very little reason to apprehend that it will give way afterwards, although it might so happen if the gas cylinder were left charged in a place in which its temperature might rise very high. The remedy for this is a proper co-efficient of safety in the strength. The purchaser of a gas cylinder ought to be able to demand, and be supplied with, a certificate from some authoritative source, or reliable independent authority, showing that the cylinder has been tested, at least, to three times the maximum pressure it is ever likely to have to endure in use. A few shillings, as Mr. W. I. Chadwick observes, would cheerfully be paid for this.

The second, and by far most probable cause of accident, is the filling up of a partly emptied cylinder with the other gas. Some months ago, being myself nervous, as a user of steel gas cylinders, on this point, I called at the offices of Brin's Oxygen Company and stated my fears, and asked for information as to the precautions adopted to prevent it. I was politely informed that the Company's workmen were very careful and never made a mistake. I retired with fears unassuaged, but confident at least of this one thing, that if the Company's workmen were ordinary human beings the liability to error was bound to exist, assurances notwithstanding.

Now the public and users generally have this matter very much in their own hands. The practice of sending back cylinders with a little gas left in them, and of getting credit for two or three feet of residual gas, is a bad one. It ought to be a universal rule to send back the cylinders empty, and then even if filled up with the wrong gas there can be no mishap. It is a good deal better to sacrifice a few feet of oxygen or hydrogen by opening the stopcock wide before returning, than to run the risk of having delivered back to one a cylinder charged with mixed gases. By the use of a simple Y stopcock tube and a couple of bottles with

pressure reducing valves, it is always possible to use up to the last foot of gas, and change over from the empty to a full bottle, even during an exhibition.

In conclusion, I would say to every lanternist, photographer, or lecturer, that the remedy is with themselves. Instead of crying out for Government stamps on bottles, or penalties for mistakes, let every user adopt the following rules and adhere to them rigidly:—

1. Buy your gas bottles only of the best firms; use steel bottles, and do not consider cheapness as the chief recommendation in purchase. Go to a reputable firm and get them to find out for you if the bottle has been tested, if so, when and where.

2. Make it a rule to send back all your bottles empty, and with the stopcock open.

3. Paint your own distinctive mark on your bottles. Let the "H" bottle be painted red, with the word hydrogen on it in black; and the "O" bottle be black, with the word oxygen on it in white.

4. When you get back your full bottle test it yourself, or by a responsible assistant, in the manner described in Mr. Baker's letter of Feb. 15 (THE BRITISH JOURNAL OF PHOTOGRAPHY), and with these precautions invariably carried out, the risk of use of compressed gas will be reduced to a minimum, if not altogether annulled.—I am, yours, &c.,
J. A. FLEMING.

Professor of Electrical Engineering in University College, London.

To the Editor.

SIR,—I was very pleased to see the report of the inquest on the late Mr. Bewley in your issue of the 15th instant, as a careful reading of the facts contained therein should allay the apprehension caused by the explosion.

Personally, I have used the gases compressed in cylinders, for lantern work, upwards of three seasons, and have not during the whole of that time had the slightest mishap, though I cannot say the same respecting a period of about thirty years, during which I used the bags.

I remember seeing the compressed gases first used in Manchester, and also seeing the first exhibition (with the compressed gases) by our premier local lanternist, Mr. J. E. Jones, followed, shortly afterwards, by a technical lantern meeting of the Manchester Photographic Society, where the question of bottles *versus* bags was thoroughly gone into, the bottles coming out triumphant, though it required the continued successful manipulation of Mr. Jones to popularise the use of the compressed gases in our city. Another of our well-known lanternists, the indefatigable secretary of the above Society (Mr. Chadwick), has lately been converted from the "darkness" of bags to the "light" of compressed gases.

After a period so extremely marked by progress, it would be a great pity to get on a "down grade" movement, but if we find the required conditions of safety in the use of compressed gases, and insist on them, our words and deeds will be signalized by advancement!

What are the conditions of safety? I should say—(1) No admixture of the gases in the cylinder; (2) Cylinders, properly tested, to stand double the pressure used in them. The suggestion to make the screws of the cylinder necks different sizes, would certainly prevent carelessness in filling the bottles, but it would not prevent filling a cylinder containing hydrogen, with oxygen (or *vice versa*) intentionally, as making a union for attachment of another size screw is easily done. Therefore we have to trust the makers for correctly filling our cylinders. Our cylinders ought to be properly and correctly tested for pressure by an independent authority, and certified accordingly; and I trust that all possible influence will be brought to bear to have enforced testing and correct filling of the cylinders, and also a distinctive difference made between the oxygen and hydrogen cylinders, so that one may not be carelessly used for the other.—I am, yours, &c.,
J. A. FURNIVAL.

To the Editor.

SIR,—We observe in your issue of the 15th instant, Mr. W. I. Chadwick writes that while it is stated this Company supplies oxygen only in black cylinders, and hydrogen in red cylinders, "he has had a dozen black cylinders containing hydrogen for one red."

If Mr. Chadwick insinuates that these bottles came from us, we beg to give a most emphatic denial to the statement; we make it our invariable rule to compress hydrogen into red cylinders only. This branch of our business, viz., hydrogen compressing, was commenced only at the beginning of this winter.—I am, yours, &c.,
T. N. HESTER,

Secretary, Brin's Oxygen Company, Limited.
Connaught Mansions, Victoria-street, Westminster.

Mr. W. TYLER, Birmingham, sends us his *Practical Hints and Photographic Calendar for 1880*. It contains, *inter alia*, a complete illustrated list of Mr. Tyler's numerous little inventions.

A PRETTY little pocket synopsis of the meetings during the present year, and which forms at the same time a member's ticket, has been introduced by Mr. J. L. Mackrell, the Hon. Secretary of the Birkenhead Photographic Association.

Exchange Column.

*. No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Wanted, a good cloth background, about nine feet by six feet, in exchange for uprights and stays of horizontal bar.—Address, W. NEWAT, Crellin-street, Barrow.

Mahogany-body lantern, four-inch condensers, four-wick lamp and limelight, two blow-through jets, ten-feet and five-feet screens, valve for compressed gas, union and key for bottle, in exchange for half-plate camera, three double backs, and rapid rectilinear lens.—Address, R. POLLARD, 101, Albion-street, Leeds.

A single stereoscopic camera, fitted with landscape lens, double dark slide, changing box to hold twelve plates, all in polished mahogany lock-and-key box, with tripod complete; will give in part exchange for a tricycle (Coventry Convertible Tandem, 1887, machine preferred).—Address, E. I. BARRS, High-street, Hailsham, Sussex.

Answers to Correspondents.

*. Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

PHOTOGRAPH REGISTERED:—

H. Grayson, Blackburn.—Design for advertisement with photograph on fancy mount.

R. BOOTHBRIDGE.—We are waiting for information.

W. J. ARCHER.—Received too late for insertion in this number.

VETRO.—Label the bottles and such a mistake will not again happen.

A. M. M.—We shall inquire into the subject and send you word privately.

W. M. PHILLIPS.—Try the first formula; the proportions are therein stated.

E. M. P.—We are at present unable to offer any suggestions respecting the lad. 1, 2, 3, 4.—Please send us your name and address, not necessarily for publication.

T. B.—A little glycerine added to the starch paste will prevent decomposition for several days.

NEW SUBSCRIBER.—Place a stop in front of the lens; you cannot use it otherwise for your purpose.

P.—Mr. E. Maybridge, of America, is at present in this country. He is to lecture at the Royal Institution and elsewhere.

WILLIAM KERR.—Immerse the print in a solution of oxalate of potash, acetic acid, and water; this will remove the yellow stain.

SIMPLICITY.—Your article cannot be printed unless as an advertisement. It is merely a means of trying to dispose of your invention.

SCRATCH.—The marks on the prints are caused by grit of some kind on the burnisher. Clean it thoroughly, lubricate a print, and try again.

S. (Lincoln).—You can, with an ordinary lead pencil, write a number on the gelatine film which will remain after the plate has been developed.

JAILER.—Nothing better than photographing the palm of the hand. Rub it smartly just before exposing, so as to render the lines clear and distinct.

T. T. L.—Your vignetting is too hard. Place your vignetter a little farther from the negative, and the results will be much softer. Report progress to us again.

PROVINCIAL.—Certainly; you ought to arrange for a visit to London during the Crystal Palace Exhibition. We can promise you a treat; at any rate, in so far as regards the newest of apparatus and mechanical appliances in general.

REV. B. P.—There are numerous freezing compounds, but that which will prove most useful to you on your arrival in the Bahamas is a simple solution of nitrate of ammonia in water, which may be used "over and over again." If you wish further details, write again.

LIGHT.—No. 2 possesses this advantage, that snow can more easily be cleaned off; but either will make a good studio. Put plain glass on the top and ground in the sides, especially if any buildings obstruct the light. Any colour of blind with fair opacity will answer.

W. G.—If the arborescent markings in the lens do not disappear under the influence of a rather vigorous warmth, then remove it from the cell, and, by adopting the means very often described both in these pages and in those of the ALMANAC, have the contact surfaces recemented.

SILK.—Immerse it in water, one ounce; gelatine, five grains; chloride of sodium, five grains. Hang it up to dry; then float for half a minute on a fifty-grain solution of nitrate of silver; dry, print, and fix as usual.

REX.—1. By substituting a larger condenser for the present one a larger picture can be shown. The size of slide capable of being projected depends entirely upon the size of the condenser.—2. We are unable to say unless we saw both lenses. You can make a trial without much trouble.

HYDRO.—1. Five inches.—2. Yes; but a little larger is preferable, to allow for marginal defects.—3. A little larger than the plate, so that no light from the lenses is obstructed.—4. Mount the lenses so that each one shall be opposite the centre of the plate when divided.—5. Stereoscopes can be had from a shilling upwards.

S. P. L.—The argentometer test for a solution of nitrate of silver may be relied upon when there is nothing else present than nitrate of silver; but it ceases to be reliable when the solution to be tested is an old printing or negative bath in which, owing to the very fact of age, there are bound to be many so-called impurities introduced as products of decomposition.

J. G. C.—For window transparencies a somewhat deeply-printed silver print will be found to answer quite as well as those that have been specially prepared on opal or glass at considerable expense. It may, in some instances, be desirable to render the paper translucent by varnishing or filling its pores with wax, but this depends upon circumstances, by which we mean the thinness of the paper and the luminousness of the subjects which are outside of the window.

W. D. inquires: "What is the best way of making a gold toning bath for wet plate lantern slides? Should the slide be placed in the fixing bath for the second time after toning? Any other toning bath more suitable I should be glad to be referred to should it have appeared in the JOURNAL during the last four or five years."—In reply: We do not advise the use of a gold toning bath for lantern slides, preferring platina instead, as, in our estimation, it gives a more pleasing tone. Place the contents of a fifteen-grain tube in fifteen ounces of water, then throw in a small bit of blue litmus paper, which will probably turn red immediately; add solution of bicarbonate of soda until blue colour is restored to the litmus; now add nitric acid drop by drop until the litmus becomes red. This constitutes a stock solution, a few drops of which added to water forms the toning bath.

MR. BYRNE, of Richmond, has had the honour of photographing Their Majesties the Queen and the Empress Frederick.

THE annual general meeting of the Photographers' Benevolent Association will be held on the 22nd instant (this evening) at 181 Aldersgate-street, E.C.

THE North London Photographic Society will hold an exhibition of the work of its members on March 5 at Myddelton Hall. During the evening a lantern entertainment will be given. Members are permitted to bring their friends.

PHOTOGRAPHIC CLUB.—The next meeting of this Club (February 27) will be the Annual Exhibition, and Mr. W. Cobb will read a paper on *Photography and Art*. Photographs for exhibition must be sent in any time not later than Wednesday afternoon, February 27.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Monthly technical meeting, Tuesday, February 26, at eight p.m., at 5A, Pall Mall East, when the negatives, developed by hydroquinone, shown by Mr. J. W. Swan, M.A., F.C.S., during the reading of his paper at the annual meeting, will be exhibited.

WALTHAMSTOW LITERARY INSTITUTE.—On Monday, the 18th instant, Mr. J. J. Brighshaw gave a lantern exhibition at the Walthamstow Literary Institute. The attendance was very large, many being unable to gain admittance. Numerous choice photographs were projected on the screen.

WEST LONDON PHOTOGRAPHIC SOCIETY.—Just when preparing for press we are in receipt of a letter from Mr. F. W. Hart, who says that the report of the meeting of the above Society which we published last week is misleading and damaging to him from undue suppression. This may be so; but the report in question was received from the Secretary, and inserted as received.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The following constitute the officers and Council of the Photographic Society, as elected at the annual meeting last week:—*President*: Mr. James Glaisher, F.R.S., F.R.A.S., &c.—*Vice-Presidents*: Captain W. de W. Abney, C.B., &c., Messrs. H. P. Robinson, J. Spiller, F.C.S., F.I.G., and H. Trueman Wood, M.A.—*Council*: Messrs. G. L. Addenbrooke, W. Bedford, V. Blanchard, Lionel Clark, F. Cobb, W. Cobb, A. A. Common, F.R.S., F.R.A.S., A. Cowan, T. R. Dallmeyer, Captain L. Darwin, T. Sebastian Davis, F.C.S., G. Davison, W. E. Debenham, W. England, J. Gale, Chapman Jones, F.C.S., Captain A. M. Mantell, J. Traill Taylor, Leon Warnerke, and S. G. B. Wollaston.—*Hon. Treasurer*: Mr. W. S. Bird.

No. 1504. VOL. XXXVI.—MARCH 1, 1889.

EXPLOSIVE SILVER AND IODINE COMPOUNDS.

THE precise connexion between the death of Mr. Bewley by the explosion of a gas bottle and the subject of chemical explosives is not clearly discernible at first sight, yet it is the case that, on the "that reminds me" principle, in more than one society or club at which the fatal accident has been spoken of the conversation has gradually become deflected into explosives in general.

It so happens that several photographic preparations—although quite innocuous in themselves—are yet separated from compounds of an exceedingly dangerous nature by only an extremely thin wall of demarcation, and upon some of these and their cognates we shall speak for a little.

A species of alarm has at various periods arisen in the minds of some who employ ammonio-nitrate of silver in photography, because of an imaginary close alliance between this compound and the deadly fulminating silver, which may render the conversion of the one into the other possible if not probable; and we know of some instances in which the photographer, seeing a dark-coloured incrustated powder surrounding the cork at its junction with the bottle containing the liquid, has been afraid to remove it for fear of the explosion that would inevitably occur had a fulminate been formed. But of this there is no danger, for something else than ammonia and nitrate of silver is required to form the fulminating compound. We say "fulminating compound" because there is another explosive other than the true fulminate of silver which is formed, concerning the comparative danger of which we are happily unable to speak from personal experience, although we know of lives having been lost by both.

An imperfect argentine fulminate, although one of a violently explosive character, is prepared by digesting recently precipitated oxide of silver in ammonia for twelve hours, then pouring off the liquid and cautiously drying the black powder in the air, having previously divided it into small portions. This is a most violent explosive, but not quite so much so as some crystals which are obtained from the ammoniacal liquid that was decanted. This liquid, after being gently heated, deposits, on cooling, small crystals which will scarcely bear touching, even whilst under the liquid. A modification of this consists in dissolving chloride of silver in ammonia, adding caustic potash in fragments, and when effervescence ceases decanting the fluid portion and washing and drying the powder. These were known as Berthollet's fulminating silver, although they are not now considered to be a true fulminate of silver, being simply oxide of silver and ammonia.

The true fulminate is formed by adding alcohol to a warm solution of acid nitrate of silver. We give a formula for its

preparation on the principle upon which sunken rocks are marked on the mariner's chart, viz., as something to be avoided when experimenting with chemicals in everyday use. Pour one ounce of alcohol over one hundred grains of powdered nitrate of silver and add an ounce of nitric acid. When the nitrate assumes a white, cloudy appearance, cold water is added to suspend the ebullition, and the powder is collected on a filter and divided into small portions. This is Brugnatelli's method; but those of Fownes and Liebig differ from it in no important respect. For example, the latter dissolves one part of metallic silver in ten parts of nitric acid, and then pours the solution into twenty-three parts of alcohol. This is heated to the boiling point, and is set aside to cool, when the fulminate is deposited in white, lustrous, acicular crystals, the weight of which, after being washed, equals that of the silver originally employed.

From the foregoing it will be seen how near to the wind photographers may sail without running foul of this most deadly compound, which only a few years ago was stated to be the most dangerous substance for which we are indebted to modern chemistry. It is certainly still the most dangerous of those cognate to photography, not excepting the iodide of nitrogen, a substance which at one time was recommended as giving a remarkable degree of sensitiveness when employed in photography. Indeed, in the earlier times, even the fulminates, not only of silver, but of the other metals, were suggested as being likely to possess marvellous sensitive-conferring properties. Friction or percussion are stated as means whereby the explosion of fulminating silver is effected, but such friction and percussion need be only very slight indeed—a touch of a feather and the fall of a drop of water upon the compound have been known to do the mischief.

We have alluded to iodide of nitrogen. We feel it to be a duty to refer to the fatal facility with which this substance can be formed. A few crystals of iodine placed in a capsule, with enough ammonia poured over it to effect its solution—and that is all. The compound arising from this simple mixture is the deadly ter-iodide of nitrogen. Such a mixture has been recommended, and is employed by many, for removing pyro stains from the fingers. When used aright, it is quite harmless, the condition of safety being found in there being an excess of the iodine. This solution was stated by the late Rev. J. B. Reade, F.R.S., at that time President of the Royal Microscopic Society, to form an agent in dissolving gold under circumstances valuable and interesting to microscopists. A drop is placed upon a microscopic slide, and a bit of gold leaf is laid thereon; this dissolves and forms beautiful tree and shrub-like growths of bright gold.

When photographers feel it incumbent on them to use iodide of nitrogen, they ought to take special care not to allow it to be placed aside where it will dry and crystallise, as in this form it cannot bear to be touched. Even the very act of throwing it away may lead to its exploding ere it is projected into the waste.

DOUBLE PRINTING-IN DEVELOPMENT PROCESSES.

COMBINATION printing on albumenised paper, when the work can be watched as it proceeds, is tolerably well known to most photographers; but in processes where the image is invisible until it is developed, it is manifest that the same plan cannot be followed, hence some method of securing accurate registration must be adopted. Many inquiries have, from time to time, been made with regard to the printing-in of clouds in platinotype and bromide paper pictures, and a similar query with reference to carbon was put at the last meeting of the West London Photographic Society. There are different ways by which the end may be attained, but, in the present article, we shall confine ourselves to one alone. It, with slight modifications, may be made available for many requirements where two or more negatives have to be combined; as, for example, in changing a background, introducing figures, or printing-in a sky.

The origin of the method to be described is due to M. Lambert, who was most skilful in combining portions of one picture with those of another in the carbon process. As the method is equally as applicable to platinum and to bromide paper as it is to carbon, we shall here describe it as we saw it worked by the inventor himself when he was here, and as we have since employed it ourselves. For our present purpose we will suppose that a large portrait negative has an objectionable background, which it is desirable to replace with a plain one, or a single figure out of a group is required.

In the first place we take a piece of thin, non-actinic paper, somewhat larger than the negative, and, holding it thereon, trace with a lead pencil the outline of the figure, and then lay it aside for the present. Next, the back of the negative is covered with thin, translucent paper, for example—*papier végétal* or *papier minéral*. The thin, paraffined paper sold by many fancy box makers answers quite well. The paper is placed, for a few minutes, between damp blotting paper to expand, and is then secured with gum to the edges of the negative. When dry it will be perfectly tight and even. Now the outline of the figure is carefully traced on the paper with a sharp-pointed pencil, only a faint line being made. For the printing, a frame with plate glass, not more than three-sixteenths of an inch in thickness, should be used, and it must be somewhat larger than the picture.

The negative is put into the frame and the sensitive paper placed upon it, and the frame closed. In placing the paper in the frame, care must be taken that one angle (it matters not which) is pressed evenly into one corner of the frame, and this should be marked with pencil on the paper, so as to avoid mistakes in its removal and replacement. Next, on the glass of the printing frame the figure must be painted round for about a quarter or half an inch—on the background portion—with oil colour, mixed with olive or other non-drying oil; Indian red is a good colour to use. In doing this, the pencil tracing on the back of the negative serves as a guide, and the paint should be kept just outside the line, and not be allowed to encroach on the figure. The yellow paper is now taken and roughly cut out for

about the quarter of an inch, first without and then within the pencil mark previously made. Thus we have two masks a quarter of an inch, or so, less than where the juncture in the picture is to be; the background one is now laid in position on the red paint, with a few pieces of glass or lead to retain it thus while exposing. This, of course, is to protect the sensitive paper outside the paint while the figure is printing. The frame is now exposed, but the printing must be conducted in diffused light, and the position of the frame should be changed from time to time.

When the exposure has been sufficient, the frame is taken into the dark room, the mask removed, and the paint cleaned off with a rag moistened with turpentine. Now, before anything is disturbed, the figure has to be painted round again, this time on the figure portion, just inside the guide line, keeping as much within it as in the previous painting it was without. This done, the frame is opened and the negative taken out. Of course, if the print were now developed it would show the figure on a white background, not, however, with an abrupt outline, but with a blurred, or rather a vignetted, one, arising from the diffusion of the light under the edge of the paint.

Supposing a plain background be desired, the sensitive paper is simply replaced in the frame, registration being secured by placing it in the same angle as before. The second rough mask is then adjusted, and the background printed-in also in diffused light, and with constant moving of the frame. It can, of course, be shaded, or otherwise, in the printing as desired. The object of the rough paper mask is simply to avoid having to apply the paint all over the portions requiring protection. By this method of masking, it will be seen that the two printings are vignetted into each other at the juncture, instead of being abrupt joins, so that a soft instead of a harsh result is obtained.

When the second printing has to be from another negative, a slightly different course is pursued. In the first instance, this negative is also covered with translucent paper; it is then placed on the first one, and adjusted to the position the two images are to occupy in the finished picture. The outline of the first, or principal negative, is then traced on the paper of the second one. Then, after the first printing has been completed, and the second mask prepared, the first negative is removed and the second one introduced, the tracing on its back serving as an accurate guide as to position.

In printing on bromide paper, artificial light, placed at some distance off, is best, and then the frame should be kept moving all the time by slowly turning it round.

WE are sorry to announce the death of an old-time photographer, Prof. P. H. Delamotte, of King's College. Many years ago (1856) Mr. Delamotte published a work on the *Oxymel Process in Photography*, which was characterised by its great practical value. In this process he was an acknowledged master; the work was illustrated by a charming picture obtained by the process in question. He was Professor of Fine Arts in King's College, and had taught art at South Kensington, some of the members of the Royal family being among his pupils. He died on the 24th ultimo, at Bromley, Kent, aged 68.

At the annual meeting of the Photographers' Benevolent Association an announcement was made that, owing to the feeble response to appeals made to the profession to establish an Orphanage Fund, it was found expedient to abandon that scheme. At the same meeting

one of the members, Mr. Hubert, advocated the employment of an Hon. Secretary in place of a paid one, but the majority of the members present, realising the nature of the arduous duties devolving upon this office, considered that the payment of the Secretary was imperatively called for, and ruled accordingly.

A SUBSTANCE which Nature terms one of the most remarkable liquids yet discovered, and which possesses properties that may render it serviceable in photographic processes, has recently been prepared by Drs. Curtius and Jay, of the University of Erlangen. Some two years ago the former investigator succeeded in isolating gaseous azidogen; but the free gas possesses such an affinity for water that its isolation in quantity seems impossible, water being of necessity a secondary product in all known reactions for producing this gas. But a pure hydrate of the substance—described as hydrazine hydrate—has been produced, and it is this liquid which possesses the remarkable properties alluded to. It is, of course, early to prognosticate as to the part it may play in the chemistry of the future; but the property we desire to draw attention to is its reducing power, which is evidently far beyond that of any of the substances at present utilised for photographic purposes—pyrogallol, hydroquinone, iron salts, &c. Hydrazine hydrate is probably the most powerful reducing agent known. The most easily reducible metals are precipitated by it from their solutions in the cold. Silver separates from strong solutions in fine compact crystalline masses, and from very dilute solutions in the form of perfect mirrors of great beauty. Neutral platinic chloride solutions are also similarly reduced, while acid solutions of iron, copper, and platinum are reduced from the ferric to the ferrous state, and so on. It remains to be seen if it can be utilised as a developer. In its concentrated form it acts on glass, cork, and caoutchouc, so that there are certainly practical difficulties in the way; whether they would be overcome by dilution we are not able to say.

For most photographic operations water of great purity is not at all actually essential, certain substances held in solution, such as carbonate of lime, being rather annoying than injurious in their effects; but there are other possible contaminations of a decidedly opposite character. Lead, for example, is one of these, and when a lead-contaminated water is used during intensification with mercury and sulphide of ammonium, the effects would be decidedly objectionable. We are led to these remarks upon reading that at one large town in this country, Bradford, water recently taken from the taps "is found by analysis, it is said, to contain from 40 to 150 grains of lead per gallon." A little sulphide of ammonium solution will rapidly indicate the presence of this impurity when a drop is added to the suspected water.

THE *Lancet* had an article lately upon the influence of the electric light upon the eyesight, founded upon the observations of Dr. Dubinski, of Kronstadt, who has for ten years had the opportunity of observing thirty cases of a peculiar ophthalmic affection occurring in young sailors, whose duties had obliged them to remain in the vicinity of electric lights. The symptoms of the disease are produced during sleep. The patient is awakened by profuse lachrymation associated with intense pain round the orbit of the eye; light has an intensely irritating effect. After a time, in from an hour and a half to three hours, the symptoms subside, and the patient is able to sleep again, to awake apparently none the worse, except for a feeling of fatigue about the eye. This is still a sufficiently distressing affection, and this account may act as a caution to all who use the electric light in photographic operations to shade their eyes from its glare as much as possible. Photography has enough of injurious accompaniments of its own without unnecessarily adding to them.

ACCORDING to the most recent experiments, however, one danger—that from the respiration of an undue proportion of carbonic acid gas, the products of combustion from gas or paraffin oil in close rooms—is not so much to be feared as once used to be thought. Following the original investigations of Dr. Richardson in this country, MM.

Brown-Léguard and d'Arsonval show that the danger arises not from this gas of itself, but from some other toxic agent accompanying it in the exhaled breath of human beings. In a large number of cases, these gentlemen found that the gas, when pure, could be inhaled in considerable quantities by human beings, dogs, rabbits, and other mammals. The authors themselves breathed for over two hours an atmosphere containing twenty per cent. of carbonic acid without any marked inconvenience.

THESE facts, nevertheless, do not contra-indicate the necessity for well-ventilated dark rooms, for there would still be the contamination by the exhaled breath of the occupants; and with gas burning in such a room, there would be the sulphur compounds also to deal with. The interest, therefore, is rather theoretical than practical; but it certainly is important to know that carbonic-acid gas alone is not a necessarily hurtful component of air when present in abnormal proportions.

AMERICAN MEN AND MATTERS.

A CAMERA Club has been organized at Rockland, Mass.

THE Case School Camera Club, of Cleveland, Ohio, has lately been organized, and has started under good auspices.

A CAMERA Club has been formed in the city of Rochester, N.Y. Both its President and Secretary are Englishmen recently well known in London and elsewhere, the former being Mr. G. H. Croughton, and the latter Mr. Peter Mawdsley.

THE Society of Amateur Photographers intends to make an exhibit at the Paris Exhibition to be held this year, and the members have engaged some one there to watch over their interests.

AN effort is being made to resuscitate the *Photographic Beacon*, a monthly journal lately published in Chicago, and conducted by Mr John Nicol, formerly of Edinburgh.

IN the *Photographic Times* of the 8th ultimo, Mr. H. P. Robinson offers strong protest against the alteration of the title of his picture, *Dawn and Sunset*, to *From Dawn to Sunset*, in which picture there is no pretence whatever to represent this implied gradation.

THE Annual Convention of the Photographic Association of America will this year take place in Boston, Mass., and will last from August 6 to 9 inclusively. Several gold, silver, and bronze medals are to be awarded for amateur work; one gold and one silver are to be set aside for foreign exhibits of portraiture. In addition, the Association are to award as a grand prize a bronze figure, value two hundred dollars, for three photographs illustrating Longfellow's poem, *Evangeline*, the size to be not less than thirteen inches, or larger than twenty-two inches.

THE following means have been suggested by Mr. Kraus, of Harrisburg, for reducing bromide prints that are too dark:—Make a saturated solution of chloride of lime and filter it. Dilute one part of this solution with four to eight parts of water, and immerse the print into it (the print being previously fixed and washed). This neither discolours the print nor the paper.

LONDON Societies, and indeed those throughout this country, have something to learn from New York, or its Society of Amateur Photographers. On the authority of the President we are enabled to state that "a ladies' night" has been arranged, on which occasion the various papers that are to be read will be by lady amateurs, as also will be the various exhibitions on that occasion, including prints, lantern slides, photographs of fancy work, &c.

THIS Society also gives smoking concerts. We should like to know whether ladies are admitted to these? Here smoking is a recognised

institution at every meeting of almost every Society, but we have no ladies' nights of the nature just spoken of in this country—more's the pity; but it is never too late to learn.

On the occasion of a flash-light group being made of the members of the Society just named—one which, we may remark, has turned out remarkably successful, judging from the specimen in our copy of the *Photographic Times*—the non-explosiveness of magnesium powder was proved to the audience by the powder having been vigorously pounded in a mortar, and its non-poisonous properties by forty grains having actually been eaten. But, *cui bono*, every one knows that magnesium is not explosive and non-poisonous; but supposing it had been poisonous, as are so many chemicals in daily use, this would not have effected its efficiency.

The veteran photographer, Mr. A. Bogardus, does not appear to entertain a very high estimate of the ability of portrait painters to pose sitters. He informs the *St. Louis Photographer* that they often bring their portrait painters along to do the posing—he was supposed to know the rules of drawing; but if they wished to see poor posing, the said painter was the man to do it. He says:—"I can name men in this city who can make better poses than all the old masters put together. Let them all stand in a row and work for hours, and I will bring a man that will in three minutes make a picture of a lady or child that shall show more grace, ease, and style than anything the gentlemen aforesaid ever conceived of. This is a pretty large assertion, but it can be demonstrated. There are pictures made every day, which for grace, ease, and beauty could not have been excelled in any age of the world."

ECHOES.

"In the multitude of counsellors there is safety" is a proverb that is generally found true, but in the case of the detective camera inquiry, reported last week, the seeker after information is pretty "safe" to get, hopelessly "fogged" by the glorious diversity of opinions offered. The enterprising Mr. Duffield is to be congratulated upon the energy and pluck displayed in carrying out his novel experiment, but I cannot think the result is worth the trouble.

To illustrate what I mean I should like to make one or two comments of my own on some of the replies, which are delightful in their variety or even direct contrariness; and the names of the different "authorities" not being given, each answer is of equal value with the rest. What, then, is to guide the searcher for help in judging between a direct "yes" or "no?"

Thus, the question is asked, "Should not the camera have a swing back?" and here the replies are charmingly graduated to meet all requirements—(a) "No;" (c) "Decidedly yes;" (d) with increasing emphasis, "Yes, two of them;" while (f) is either amusingly cautious or else is indulging in a little gentle sarcasm when he suggests, "If it would work automatically." Would that a good many photographic "properties" would work automatically!

Then, again, in reply to the query, "Do you think it necessary to have a finder?" One correspondent says, "A finder is quite needless;" the next, "A finder is very necessary." The next one again does "not see the advantage of two finders," and his immediate follower thinks "two finders so essential that I shall have an extra one put in," &c. So that any one who is about to fit himself up with a detective outfit may make up his own mind as to what he really wants, and then consult Mr. Duffield's authorities with perfect certainty that his decision will be found backed. Yes, in that sense there really is perfect safety in the multitude of counsellors.

I think it will strike many readers of the JOURNAL, especially old "lantern hands," that Mr. George Smith is somewhat unnecessarily dogmatic in some of his remarks on the subject of mixed gases. A harmless explosion resulting from the use of a home-made Hemmings's safety jet—never absolutely safe by the way—and the equally innocuous fracture of a soda-water bottle after firing many charges of gas in it, may be sufficient to warrant a nervous youth in "abandoning mixed gases for ever," but the two incidents are certainly not sufficient *per se* to condemn the use of such a mixture by more careful or less timid hands: nor do they entitle the operator to start up nearly forty years

later with a "bogy" consisting of a couple of unsuccessful schoolboy experiments dressed up for the occasion.

There is, I grant, little to recommend the employment of mixed gases at any time, or in the most careful hands, and it is not with the intention of arguing in favour of the practice that I allude to Mr. Smith's remarks, but merely to point out that the conviction he has formed "that mixed gases cannot be burned safely, no matter what precautions are taken," is decidedly a *non sequitur* in his case. The fact remains that mixed gases have over and over again been burnt "safely," if immunity from accident is taken as the measure of safety.

But his remarks on the subject of explosions from back pressure are still more extraordinary, diametrically opposed as they are to the belief and experience of every practical lanternist. "Explosions with bags," he says, "never happen from . . . back pressure." Then he goes on to explain what "always happens," namely, that the bags that explode are "always" filled with mixed gases, hence the trouble. Of course, if Mr. Smith is "always" behind the scenes sufficiently to so definitely locate the cause of all the gas explosions that occur, I can have little to say in contradiction, but I know the news will be a revelation to a good many operators who have made the mixed gases, back pressure, safety valves, and explosions generally, a careful study, instead of being scared by every foot of gas that explodes without hurting them. Here, again, it would have been safer to suggest a possible truism, rather than to dogmatise so severely. "Always" is a very definite term, and does not leave room even for the possible "exception" in the form of an accident that might prove Mr. Smith's "rule."

Whatever can be the matter with our good friends, the proprietors of *Anthony's Bulletin*? The "stock house" of that name I believe to be one of the, if not the, oldest in America, as well as one of the most enterprising and up to the times. Yet I find an article from their *Bulletin* opening with a statement that "lens flanges are never made with the same threads for the same size lenses of different makers." "Never" is just as strong a term as "always," and quite as objectionable in connexion with a statement that is not *known* to be absolutely correct. Have Messrs. Anthony, or their editors, never heard of the "standards" of the Photographic Society of Great Britain? and can they be unaware that many, or most, of the English opticians, as well as several Continental ones, have adopted those standards, both as applied to diaphragms and to flanges? If they are unaware of this, the information may be useful to them; if American opticians only are referred to as being behind the times, that should have been clearly stated in the article referred to, which says that a certain thing is *never* done, whereas in Europe, at least, it is done *daily*.

Then they go on to say that "American, English, and other European dry plates are all made to suit the whims of some particular set of individuals, without any regard to the tourist," &c., &c. Now, a more flagrant libel on English plate makers I cannot conceive. So far as I am aware, the only measurements in vogue are the English inches and the French centimetres, and plates of *any recognised size* by either measurement are made and stocked by most English makers and dealers. As regards "recognised" sizes, there are perhaps far too many English ones, but I have never heard of an American size that is purely American and *not* English, so that I am quite certain that American tourists have no ground for complaint in not being able to procure plates in England—or elsewhere, for that matter—to fit cameras built in the States.

The American has a way of *calling* his plate a different size to what we are accustomed to call it here: thus, 4×5, 5×8, 8×10 are his favourite sizes, and correspond with our 5×4, 8×5, and 10×8. A smart Yankee thought to take it out of an English salesman one day on this matter, but the "Britisher" was his match. Having ordered a dozen "four-by-five" plates, he was handed a packet conspicuously labelled 5×4; so, returning them to the shopman, he remarked, "I guess, young man, you've given me the wrong size—I want them four by five." "Quite right, sir," was the reply; "you will find, if you turn them round, they are four by five."

The gist of the article, however, is in the recommendation to adopt the practice of stating formulæ in quantities of a solution of such-and-such substance of a certain specific gravity, in order to avoid the difficulties arising from the existence of certain salts containing

different proportions of combined water. The practice is one largely adopted by chemists—i.e., by men who require the greatest accuracy, and who can attain it best by that means; but they are also, by training, competent to see that their specific gravities are correct.

But a more unpractical recommendation to the ordinary photographer it would be difficult to make. To him the operation of making a solution of any salt of a definite specific gravity, even if he possessed a hydrometer, would be perhaps greater than that involved in ascertaining whether his carbonate of soda contained ten or six equivalents of water, or none at all. The difficulty raised is, in fact—here, at least—chiefly an imaginary one. JUNITS.

AN ABSOLUTE STANDARD SENSITOMETER.

Some little time ago the writer determined to try and make an instrument which should test the sensitiveness of photographic films in such a way that it might be stated in terms of positive measure, and not, as heretofore, in reference to some arbitrary standard. "Ten times" and "twenty times" used as measures of sensitiveness may mean anything, they certainly mean nothing definite. "Rapid," "extra rapid," give some idea of the uses to which the plates may be put, but only vaguely, while the "rapid" of one maker probably differs widely from the plate of the same name by another maker. It seemed to the writer that photography had now attained a position when plate users might fairly say to plate makers, "Send me some plates of such-and-such a sensitiveness." Just as an engineer can say to a steel maker, "Send me some steel of such tensile strength;" or the electrician, "Send me some copper wire of such conductivity." It is true that there is a sensitometer in the market which is largely used, but it has an arbitrary scale, based on no natural scientific standard, and depends, so far as one instrument is comparable with another, upon the careful matching of a series of tests, which are liable to change, so that even if the same instrument is used, the readings of to-day are not strictly comparable with those of a month ago.

The writer experimented with various ways of forming time, and found it much difficultly and uncertainty in getting anything that could be reproduced with certainty time after time, that he came to the conclusion that another principle of testing must be adopted. On thinking the matter over, it appeared to him that instead of varying the intensity of the light acting upon various portions of the plate, the better way would be to let light of the same intensity act upon various portions of the plate for different lengths of time. The result, so far as the action of the light is concerned, will evidently be the same, while the latter plan has the advantage of being possible to be repeated with exactness in any place and at any time, and also of more correctly representing the circumstances under which the plates would be used.

The principle of the machine is very simple, is based upon scientific laws, and may be stated in such terms that a test made in England is strictly comparable with one made in America, and one made to-day with one made one hundred years hence.

Briefly, the plan is this:—A sensitive plate is placed at a fixed distance from a standard light, and small portions of the plate are exposed for gradually increasing periods of time to that standard light. Thus the times necessary to express the sensitive value of the plate are—(1). The light; (2). The distance between the plate and the light; and (3). The time that any portion of the plate was exposed to the light to produce when developed a visible image.

There is, of course, a somewhat uncertain point at either end of the operation, viz., the intensity of the standard light, and the energy of the developing solution. But these are incidental to any system of testing, and will probably be improved, if not made practically perfect, in the near future, while the testing itself is based on natural laws, and is correct beyond possibility of doubt. In the meantime it would be well if the Photographic Society would decide whether a standard candle or Harcourt's pentane standard should be used as the standard light, and what solution should be used as the standard developer.

The apparatus devised to carry out this system of testing is as follows (it is made to test quarter-plates, but can be made to take larger ones if wanted):—B is a kind of box containing the mechanism; S is a very thin glass plate in which are cut a series of figures from one to fifty. A series of shutters (one for each row of figures) works closely in front of the plate, and outside is one large shutter which closes up everything. P is a pendulum beating half seconds. D is a drum round which is wound a cord with a weight, W, at the end of it. This weight drives the mechanism. It is an escape-wheel controlled by the pendulum, having a pinion fixed to it, which gears into a wheel on the arbor of the drum D. Also on the arbor of D are five pinions, and on the backs of the five shutters are racks gearing with these last pinions. The pinions are so arranged that they come into action one after the other, each one starting when the one before it has lifted its shutter to the top. At each beat of the pendulum

one of the shutters is lifted so as to expose one of the figures, beginning with fifty and ending with one.

The outside shutter, which is not shown in the sketch, is held up by a catch, which is released half a second after the last figure on the plate has been exposed to the light.

The method of working is as follows:—The instrument is supposed to be placed on a table in a dark room, so that the weight can fall freely the length of the cord. The weight is wound up and all the shutters let down. The weight drum is locked by a catch till all is ready to begin the test. The plate to be tested is placed behind the figure plate and pressed up by the spring-back. The standard light is lit, and placed at

the determined distance. The outer shutter is raised till held by the catch. Finally, the trigger is pulled, when the five shutters will rise one after another, in steps half a second apart, until all the fifty figures on the plate have been exposed, and then the outer shutter falls and prevents further action on the plate, which is then taken out and developed. Suppose the lowest figure visible be twenty-five, its sensitiveness may be stated thus:—"The plate will give a developable image when exposed to a standard candle (or pentane light) at a distance of, say, ten feet for twenty-five half seconds."

It will be seen that the terms of this statement are such that they can be used and verified by any person, in any part of the world, without the instrument used having been previously compared. In other words, it is a natural and absolute standard.

The instrument may also be used for another purpose. If a batch of plates be carefully standardised then the instrument may be used to determine the chemical energy of various artificial lights, or of daylight on

different days, on different times on the same day, or of moonlight. In the case of daylight it would be necessary to diminish the full intensity by limiting the size of aperture through which light got access to the plate. But, again, all these values would be strictly comparable one with another in terms of time, distance, and size of aperture.

Many details of construction have necessarily been omitted in describing the instrument here, but if any reader wishes to know more about it, the writer will be pleased to answer any question that may be addressed to him.

J. W. NEWALL.

HYDROQUINONE AS A DEVELOPING AGENT.

[A Communication to the Photographic Society of Great Britain.]

I AM aware that hydroquinone is no longer an unfamiliar word in the ears of those who attend the meetings of the Photographic Society, and that many of the members have already experimented with this chemical; but I have a strong impression that its merits as a developing agent are not as widely or as clearly recognised as they deserve to be. I believe that these are both many and great, and, in fact, that of all developing agents hydroquinone is probably, on the whole, the best, and, therefore, I have ventured, on the invitation of your treasurer, to bring before you some evidences of its usefulness.

Hydroquinone is, as you know, a derivative of benzene. Its composition is $C_6H_4(OH)_2$; that is to say, it is a compound in which two of the hydrogen atoms of benzene are replaced by two hydroxyl radicals, and, as these hydroxyl groups occupy the first and fourth places in the theoretical benzene ring, the compound is called Para-di-hydroxy-benzene. Paradihydroxybenzene is a descriptive, but not an euphonious name, and hydroquinone is too long for the impatient photographer, who abbreviates hyposulphite to hypo and pyrogallol to pyro. However, the want of brevity in designating hydroquinone is perfectly met by its quite orthodox synonym, quinol—a word as easy to pronounce as pyro.

Hydroquinone, or quinol as I shall hereafter call it, crystallises in two forms, melts at 163° , distils without decomposition, and is soluble in water, alcohol, and ether.

But of quinol in its chemical aspect I am not going to say anything beyond this: that it is now procurable as a commercial article in a condition of sufficient purity and stability, and at a sufficiently moderate price to bring it into close competition in these respects with ferrous oxalate and pyrogallol.

When quinol is dissolved in water and exposed to the air it undergoes somewhat rapid decomposition by absorbing oxygen, and in consequence it loses power as a developer, more or less, according to the extent to which decomposition has gone, and it correspondingly changes colour, at first to a light and at last to a dark red brown. The change produced by contact with the air of an aqueous solution of quinol exactly corresponds to that which takes place in a solution of pyrogallol under similar conditions, except that, as Mr. Bolton has pointed out, the quinol solution keeps bright, even when the decomposition has advanced very far, while a pyrogallol solution turns muddy, as well as dark-coloured. But in a well-closed bottle, and especially if a small proportion of citric acid is combined with it, the solution keeps very well—as well or better than any other developing agent.

In discussing the merits of different kinds of developing solutions, it is necessary to bear in mind the properties that ought to be possessed by an ideal developer, but it is not possible to range those properties immovably in the order of their importance, because what is important in one class of photographic work is not important in a different class.

In nine cases out of ten, however, one of the most desirable properties in a developer is the property of *energy*, by which I mean the power to bring out the faintest impact of light, and give full effect to the sensitiveness of an extremely sensitive plate. If we rank one quality above another at all, I think we must put that in the highest place.

I do not forget that there are cases in which superior energy in the action of the developer is of no value. For example, in that class of negative employed in photo-mechanical work, where clear lines are to show crisply through an almost opaque field, there the property I mention is not a virtue but a vice. But that is an exceptional class of negative; and, looking not at the exceptions, but at the rule, there can be no question that the possession of superior power to develop weak impressions of light is, as a rule, more important than any other quality.

The sense in which I am using the word energy does not necessarily imply rapidity of action in the developer, although rapidity of action is generally an accompaniment, and a desirable accompaniment, of

energy of action. By energy, I mean the power, independently of time, to ultimately bring out to the utmost extent the faintest effect of light.

But there are certain properties that are *always* desirable in a developing agent. 1. It is always desirable that the developing agent should only act where the light has acted, and consequently not produce fog. 2. That in so acting, a certain degree of density, culminating in opacity, should be producible by it. 3. That it should be possible to modify its effect so as to compensate for errors of exposure, and obtain the degree of density required. 4. That it should be without detrimental action on the film in which the sensitive material is embedded. 5. That the colour of the image should not be photographically deceptive or bad. 6. That its action should, within reasonable limits, be rapid. 7. That it should be innocuous. 8. That it should be cleanly in manipulation. 9. That it should be stable. 10. That it should be cheap.

Besides these there are other properties which are *generally* advantageous. Rapidity of development is one of these, but there is another far more important than that, and it is the property of giving a gradation of density perfectly proportional to the degree of the light's action. That property is, of course, essential in almost every case except the one I have mentioned, in which only black and white are to be reproduced.

For the purpose of illustrating the capabilities of quinol as a developing agent, I have had made a series of negatives. These negatives bear on many of the points I have mentioned, and I feel sure will be found, by those who examine them, to be full of interest. I am sorry that it is so difficult to show negatives properly in a meeting like this, for the full measure of information can only be extracted from them after a somewhat long and minute examination, and comparison one with another and with the different conditions under which they have been produced all the while remembered. We must do the best we can under the circumstances, which will be to pass round those which are, so to speak, self-contained, and to leave the rest on the table to be examined, by those who care to examine them, after the meeting. I will do what I can to describe their characteristics, but a careful examination of the negatives themselves is the only way to fully appreciate the points sought to be brought out by them.

That you may have full confidence in the normal character of the results shown by these negatives, I may say that the experiments were carried out with the greatest possible care by Mr. John Green, the photographer attached to Mawson & Swan's plate works, one of the most painstaking and fastidious operators it has ever been my fortune to come into contact with.

I will, in the first place, pass round two negatives, Nos. 1 and 2, which illustrate the point that I have given the first place to, in the order of merit of the properties of developers, namely, energy.

The two plates are alike; they are Mawson's "Castle" plates, and they were exposed for the same time to the same object—in fact, they only differ in the mode of development.

No. 1 is developed with ammoniacal pyro of the most energetic composition compatible with a good quality of image.

No. 2 is developed with quinol solution compounded on the same principle; that is to say, with the object of getting the best possible quality of image, and containing in each ounce of distilled water—

Quinol	2 grains.
Caustic potash	4 "
Sulphite of soda	6 "
Citric acid and bromide of potassium (each) ..	$\frac{1}{4}$ grain.

If some of the qualities ordinarily required in portraits and landscapes, and, in fact, in all half-tone photographs, had been disregarded, it is quite probable that more detail still could have been brought out in the deeply shaded parts of the picture, but as it is, the pyro and the quinol are almost exactly on a par in the degree to which detail is developed in the least-lighted portions of the negatives. In other respects the quinol has the advantage. The colour of the image is better, and there is a character about it that forcibly reminds one of a good collodion negative. It is perfectly clear and clean in the non-lighted parts, and would, no doubt, yield a print in half the time required for the pyro negative.

I have here two small plates which were each exposed for the same time in the actinometer. One has been developed by a strong pyro developer—the "Castle" formula—and the other by quinol. In each case development has been pushed to the fogging point, and with the result that there is no difference in the extent to which the actinometer scale is developed. In both plates the fourth column of figures is complete, and there is the ghost of an image of two of the figures in the fifth column.

Mr. Green suggests, and his idea has been amply supported by

experiment, that the limit of developable actinic effect is, with a given plate, the fog limit, and that therefore it may be taken as a law that if different developers are used, each strong enough to produce fog, and if the action is continued to the fogging point, there will be no difference in the extent to which feeble light impressions are brought out. There may be difference in the staining effect of one developer as compared with another, and that may greatly mask the true photo-chemical effect; and, in fact, there is such a difference in the case of the two developers here compared. The pyro developer stains the film much more than the quinol developer, but so far as the true photo-chemical effect is concerned there is no difference. J. WILSON SWAN, M.A.

(To be continued.)

THE PROPERTIES OF DETECTIVE CAMERAS.

No. II.

CONTINUING our summary of last week of the properties of detective cameras. In reply to the question:—

17. Is it not desirable that the shutter should be so constructed that the foreground receives more exposure than the sky?

(a) "A diaphragm shutter working between the lenses is best; this will expose both alike."

(b) "It is desirable to give more exposure to the foreground than to the sky, but shutters so constructed necessarily work comparatively slow. I have had several, and the fastest was about one-fortieth of a second."

(c) "Do not think any such arrangement possible for very quick exposure."

(d) "Not necessarily; an instantaneous picture generally shows uniform lighting."

(e) "Do not think it cuts any figure in shutter work."

(f) "Yes; this an imperative need, and one which the dealers should respect."

(g) "No; the most satisfactory work will be obtained with a shutter that distributes the light evenly."

(h) "I think not for detective work."

(i) "Theoretically advisable, practically unnecessary."

(j) "Yes, if you use the camera only one way; if used reversed, one side receives more light than the other. A round opening is best all around, if you cannot shift the shutter."

(k) "It is an advantage in some subjects; with water in the foreground. Uneven exposure would give the reflection greater value than the sky."

(l) "I should hardly think so, as, for instance, in water and street views in summer the foreground requires in bright sunlight even less exposure than the sky."

18. On what part of the camera should the release of the shutter be?

Nineteen say on the side; nine on the bottom; two on the top.

(a) "On top or the right side. Mine is underneath, and is very unhandy on that account."

(b) "On the side, not on the top or bottom."

(c) "I like it best on the bottom, as it is less likely to be set off by accident."

(d) "Not on the camera at all; the chance of jarring in a moment of excitement is very great. It should work by the pressure of a bulb held in the hand which does not touch the camera."

(e) "I prefer right hand side, about two-thirds distance from the bottom, as this enables you to have use of the hand to steady and the thumb to make the release."

(f) "Is not this purely a matter of convenience?"

(g) "On the side, and to be worked by a movement backward, not sidewise."

(h) "I prefer it on the next side to the right of finder."

(i) "Underneath, so that the victim does not know when he is shot."

(j) "Depends on wish of operator."

19. Please give the formula of the developer you use.

Pyro and potash, or pyro; soda and potash seem to be the favourite developers.

(a) **No. 1.**
Sulphite of soda 1 ounce.
Water 5 ounces.

No. 2.
Carbonate of soda 1 ounce.
Water 8 ounces.

Normal developer: No. 1, 1½ ounces; No. 2, 1 ounce; pyro, dry, 4 grains.

(b) Equal parts of—
No. 1.
Hydroquinone or pyro 10 grains.
Water 1 ounce.

No. 2.
Carbonate of soda 40 grains.
Water 1 ounce.

And the ferrous-oxalate developer, i.e., one part of saturated solution of ferrous sulphate and three parts of potassic oxalate.

(c) Pyrogallie acid 6 grains.
Sulphite of soda 30 "
Carbonate of potash 13 "
Carbonate of soda 5 "
Bromide of ammonium ½ grain.
Citric acid 1 "
Water 1 ounce.

(d) **No. 1.**
Pyro 50 grammes.
Hydroxylamine chloride 6.5 "
Water 500 c.c.

No. 2.
Sulphite of soda (crystals) 100 grammes.
Carbonate of soda (crystals) 200 "
Water 500 c.c.

Normal developer. For use, take 1 drachm each of Nos. 1 and 2, and add 2 ounces of water.

(e) **No. 1.**
Pyrogallie acid 1 ounce.
Sulphite of soda 4 ounces.
Sulphuric acid 1 drachm.
Water, to make 16 ounces.

No. 2.
Carbonate of soda 2 ounces.
Carbonate of potash 2 "
Water, to make 16 "

(f) **Potash Solution.**
Carbonate potash (granular) 15 per cent.
Sulphite soda (crystals) 10 "
Distilled water 75 "

Commence with using one-half of the quantity of pyro solution used to begin development, and increase gradually to the full amount, 8 drachms in 4 ounces of water, if necessary to obtain the desired contrast.

(g) **Pyro Solution.**
Pyrogallie acid 5 per cent.
Sulphite soda (crystals) 20 "
Distilled water 75 "

For time exposures, use 2 drachms in 4 ounces of water, and increase to 8 drachms gradually if intensity of negative appears too weak.

For instantaneous and portrait work, commence with 1 drachm in 4 ounces of water until development starts, when increase gradually to the full amount — 8 drachms.

(h) **Hydroquinone Solution.**
Hydroquinone 2.25 per cent.
Sulphite soda (crystals) 10 "
Distilled water 87.75 "

Use 2 ounces with 2 ounces of water; add 3 to 6 drachms of potash solution. Development is slow at first, but once started the negative gains density rapidly. Continue development further than with pyro, as density is lost in the hypo. The mixed developer can be used repeatedly, and does not cloud nor stain.

(i) Sal soda 1 ounce.
Sulphite of soda 1 "
Water 15 ounces.

To 2 ounces of the above add 2 ounces of water and 6 grains of dry pyro.

(j) Granulated carbonate of soda 4 grains.
Pyro " sulphite of soda 8 "
Water 1-3 "
Water 1 ounce.

(k) **No. 1.**
Hydroquinone 48 grains.
Alcohol 1 ounce.

No. 2.
Sulphite of soda (crystals) 2 ounces.
Carbonate of potash, c.p. 3 "
Water 12 "

Normal developer No. 1, 1 drachm; No. 2, 2 drachms; water, 2 ounces. If not strong enough, the hydroquinone can be increased up to 2 drachms.

(l) **The Ladies' Developer.**
Hydroquinone 1 gramme.
Carbonate of soda 3 grammes.
Carbonate of potash 4 "
Sulphite of soda 7 "
Water 100 cc.

(m) Pyro and soda, or pyro and potash; either works well. The latter, however, needs a little care not to fog sometimes the high lights.

20. Please state your manner of using it (weak, normal, or strong) in summer and in winter.

The general custom is to begin weak, and as soon as details begin to appear, flow the plate with normal solution, and add, if necessary, either or both of the solutions as may be required.

(a) "The temperature of the solution is one of the most important factors. In summer it should be as cold as possible at starting, as it gets warm enough as the development continues. In winter it should be about 65°, and stay so. I generally begin with a well-diluted solution, and build up as required."

(b) "In summer, I generally succeed in bringing the picture out with a weak developer; in winter, normal, warmed."

(c) "Either method, with the formulae (b), will give good results. I prefer to start development with normal developer, and as soon as density is obtained get detail by treatment with dilute alkali. Potash or ammonia give equally good results."

21. Have you ever used in detective camera work ferrous oxalate, hydroquinone, or hydroxylamine developer? What has been your experience?

The majority answer they have not used either of these developers.

(a) "Have used all of them with perfectly satisfactory results."

(b) "I prefer ferrous oxalate for all work to anything else; have used many formulae, and always returned to my favourite contented with it."

- (c) "Yes! all kinds of experience."
 (d) "Ferrous oxalate gives me weak negatives; hydroquinone fogs."
 (e) "Unsuccessful with ferrous oxalate; successful with hydroquinone."
 (f) "I used ferrous oxalate in 1834 with good results, but it was too slow and was difficult to get detail out in the shadows. I have used hydroquinone to a limited extent, but have found it much slower than pyro."
 (g) "Never used ferrous oxalate after trying pyro and potash. I believe in using one developer—first, last, and always. Get a good one, and stick to it until you can get your negative every time, or most every time."

(To be continued.)

FIFTY YEARS' PHOTOGRAPHY.

In 1834 Daguerre attempted to float a company to work his process, for at this date he announced that he had at last overcome all difficulties. The public were incredulous, and so the company was never established. It was different with the scientists of that day. They foresaw the capabilities of the new-found art; and in Arago, the famous astronomer, Daguerre found a most excellent champion. It was in a large measure due to his personal efforts and his great eloquence that the French Government granted to Daguerre a life-pension of 6000 francs. Isidore Niepce received one of 4000. This was given on the understanding that the whole world was free to use the discovery about to be divulged by Daguerre. It is a fact worthy of being noted that Daguerre patented his invention in England. Was this in revenge for Waterloo?

It would take up too much time to go into details regarding the actual process; suffice it to say, that in the original method iodide of silver, produced by exposing a silvered plate to the fumes of iodine, was made use of, and development was by means of the fumes of mercury, while the unacted-on iodide was removed by a solution of common salt. Subsequently, by the use of bromine in conjunction with the iodine, a more sensitive surface was obtained, and the salt solution replaced by hyposulphite; further, the image was strengthened by a deposit of gold. This was due to Fizeau. From what has been said it will be seen that Daguerre's process, as at first brought forward, was not altogether a very perfect one.

Before we leave Daguerre we may briefly state that he retired from active life, or rather left Paris and settled down at Bry-sur-Marne, shortly after the pension had been awarded him. He married an English lady, Louisa Arrowsmith, but had no family. In the church at this place a canvas five yards square testifies to the handiwork of the dioramic painter. It is placed behind the high altar, and being lighted from above several optical effects are brought into play. The subject here depicted is the interior of a Gothic edifice. He still experimented, and, in 1844, he announced he would be able to take a horse at full gallop. He tried hard to fix the colours in pastel work, so as to do away with the protecting glass; but this problem remains practically unsolved to this day. In passing, I may mention there seems to be at the present moment an attempt to introduce pastel work by our local artists. This class of work has always been a favourite one with French artists. Perhaps some of our members may take the matter in hand, and bring renown to our Association, succeeding where the illustrious Daguerre failed. Daguerre died suddenly on July 10, 1851, in the prime of life. In the cemetery at Bry-sur-Marne a monument was erected over his remains by the *Société Libre des Beaux Arts* in the year 1852. In 1883, a succeeding generation has erected at Cormeilles-en-Parisis a statue commemorative of Daguerre and his work. It is erected on a small open place opposite the house where he was born, and consists of a pedestal some six or seven feet in height, surmounted by a bust in bronze, the work of the sculptor Capellari. On the pedestal are the dates 1789 (year of Daguerre's birth) and 1843 (year in which the statue was erected). The actual date on which the inauguration took place was Sunday, August 26. The portrait now on the screen is taken from a daguerreotype secured by Mayall in the year 1846.

Although when treating of Niepce we made no reference to the memorial which France, assisted in some measure by the whole photographic world, has erected at Chalon-sur-Saône, it was not from any overlook, but seeing this recognition by posterity of a great man did not take place till after homage had been done to Daguerre, we thought it better to refer to Niepce's memorial at this point. A good idea of the original statue will be had from the transparency now shown. The inauguration of this tribute took place on June 21, 1885, and was made the occasion of a considerable amount of ceremony. The artist, who was good enough to do the work gratuitously, was M. Guillaume. The statue, which is in bronze, was cast at the famous workshops of Barbadienne, of Paris. It seems to me that France is much more zealous of the honour of its great men than we are. Our countryman, Talbot, who did equally good work, and who was as early in the field with his discoveries as Daguerre, has, as yet, not had that recognition which ought to have been rendered him long ago. How comes it that no commemorative statue has been erected to the man who shares with the Frenchman, whose career we have just been considering, the honour of being the discoverer of photography?

* Continued from page 128.

Let us consider briefly Talbot's work, and I think we shall see how justly entitled he would be to the recognition I have spoken of.

Henry Fox Talbot was born in the first year of this century. In 1821 he graduated with honours at Cambridge. It was intended that he should have a political career, and for two years he had a seat in Parliament; but his instincts were scientific, not political. In 1834 he retired from public life and devoted himself to scientific research. He was a member of the Royal Society and contributed many important memoirs to that important body. The communication which interests us more especially was the one which was read on January 31, 1839, and which was entitled, *Some Account of Photogenic Drawing; or, the Process by which Natural Objects may be Made to Delineate Themselves without the Aid of the Artist's Pencil*. This was followed by another communication on the 21st of February, when the method of preparing the sensitive paper was given, for Talbot made use of a paper support, whereas Daguerre and Niepce had employed metal plates. The fixing of the picture Talbot effected by means of a solution of common salts, or solutions of bromides and iodides. In the introduction to his *Pencil of Nature* Talbot asserts that as far back as 1835 he had secured pictures of his residence, Lacock Abbey, in the camera. The manner in which he puts this fact is well worth quoting. He says, "This building was the first that was ever known to have drawn its own shadow."

We have had a lantern slide made from the actual picture of Lacock Abbey figuring in the *Pencil of Nature*, and we will now have it thrown on the screen. This picture is only one of a series I hope to bring before you at some future time, as I intend having transparencies made from all the photographs in the *Pencil of Nature*.

Talbot's process possessed one great advantage over that of Daguerre's. By his system he was enabled, having once got the original picture, to reproduce it over and over again. The first picture had the lights and shades reversed, and to this the now familiar name of negative was given, while to the copy, with the lights and shades as in nature, the term positive. These terms were introduced by Sir John Herschel. The process which now bears Talbot's name—Talbotype, and which was designated by himself Calotype—was first communicated to the Royal Society, June 10, 1841, and whereas in his photogenic drawing Talbot employed silver chloride in the presence of silver nitrate, he now had recourse to silver iodide. Briefly described, the preparation of the sensitive paper was as follows:—Writing paper was in the first instance brushed over with a solution of silver nitrate; when dry it was dipped into a solution of potassium iodide of a certain strength; after drying, to render it sensitive, a solution of what Talbot called gallo-nitrate of silver was brushed over it, this operation being done by candle-light. The paper could be used either in a moist or dried condition. After exposure in the camera, to render the latent image visible, the gallo-nitrate solution was again resorted to. This developer was made as follows:—One hundred grains of silver nitrate were dissolved in two ounces of water, and strong acetic acid to the extent of a sixth of the volume of solution was added. This was called A. A saturated solution of gallic acid in water formed solution B. A and B immediately before use were mixed in equal quantities, and this formed the gallo-nitrate developer. It is now pretty certain that the Rev. J. B. Reade had also adopted a similar mode of development, and in point of time was actually before Talbot, and on this point an attempt was made to render Talbot's patent for his process invalid. In a lawsuit it was decided that Talbot had the better claim, seeing the reverend gentleman had not published his method in a properly recognised manner.

A great advance in the proper fixing of the pictures was arrived at when hyposulphite of soda was employed instead of the bromides and iodides. Sir John Herschel had, as far back as 1819, shown that these silver compounds were soluble in a solution of the salt in question, but the fact, some way or other, was overlooked till Sir John called attention to it. In the year 1840 the hyposulphites had been known for some considerable period, Chausser, in 1799, being the first to prepare them. There are several reactions by which they may be obtained, but we refer only to one. The sodium salt may readily be obtained by passing sulphurous acid gas into a solution of sodium sulphide.

It would be beyond the limits of the present communication to individualise all the various modifications of calotype that were from time to time brought forward. In some cases the paper, to render it more translucent for printing purposes, was waxed before being sensitised instead of at the end of the operations, when the negative had actually been secured. Suffice it to say, that the paper process held its own till the year 1857, when the advent of collodion altered completely the character of photographic operations. There are other matters, however, to refer to before we can approach this era in the history of photography. To return to Talbot. In addition to the *Pencil of Nature*, he published another work, illustrated by silver prints—*Sun Pictures in Scotland*. This was in 1845, and one of the most interesting pictures in the collection is now shown by means of the lantern. It represents Walter Scott's monument in Princes-street, Edinburgh, as it appeared in October, 1844. It was then in course of erection, and the scaffolding surrounding it is well seen in the picture. All the views in the sun pictures would be particularly interesting to reproduce for showing in the lantern, and I hope to have this soon done. The work is lying on the table for the inspection of members. In addition to calotype, an engraving process was devised by Talbot, as also a very sensitive plate which was able to record the printed matter of a paper which had been fastened to a wheel and which was made to revolve

rapidly, the whole being illuminated for an instant by a discharge from a Leyden battery; this was in 1851. The details by which this result was obtained are published in the *Athenæum* of December 6, 1851. He devised also a method of calotype whereby positive pictures were obtained in the camera.

As already indicated, Fox Talbot did not confine himself altogether to photography; he was a mathematician of the first rank. He was one of the first who, in conjunction with Sir Henry Rawlinson, deciphered the cuneiform inscriptions brought from Nineveh. In 1834 and 1835, we find that he has papers, *Experiments on Light*, and *On the Nature of Light*, and, in 1872, we find that he has the following papers:—*Notes on some Anomalous Spectra*, *On the Early History of Spectrum Analysis*, and *On a New Mode of Observing Certain Spectra*. He seems to have been a busy man all through, and he died full of years and honours on September 17, 1877. Before proceeding further it should perhaps be mentioned that in 1852 he renounced his patent rights, and gave, with certain reservations, the right to work his process free to his countrymen.

We have already referred to Sir John Herschel's application of the now universal solvent of the unacted-on silver salts, viz., hyposulphite of soda, let us see what part he played in the drama of photographic discovery. The name of Herschel is so intimately connected with the science of astronomy, that the photographic work of the younger Herschel, as he has been called, is on this account not so fully realised as it deservedly should be. It is an ascertained fact, that as early as 1839 Herschel obtained a camera image of his famous telescope on paper prepared with carbonate of silver, and fixed with hyposulphite. He first suggested the use of glass plates in photography. He was the originator of the various iron processes. He experimented largely in the direction of colour photography, studying the action of the spectrum on all kinds of susceptible substances. The colouring matter of flowers was also dealt with by him in a similar manner. To detail all Herschel's discoveries would require a complete paper by itself. Many of the processes devised by this investigator have dropped out of sight, but his cyanotype, or blue process, remains to this day, and is largely made use of by engravers in copying plans. The platinotype process of Wills is, in reality, based on the fact first enunciated by Herschel, that light reduces ferric salts to the ferrous state. The salts of mercury were also pressed into the photographic service by this illustrious scientist. He it was who first showed the bleaching action of the bichloride of mercury on a silver print; this was in 1810. W. LAMB, JUN.

(To be concluded.)

LORD RAYLEIGH ON EXPERIMENTAL OPTICS.

No I.

Larry Saturday, in the course of a lecture upon *Experimental Optics*, delivered at the Royal Institution by Lord Rayleigh, F.R.S., the speaker said that Sir Isaac Newton, in his experiments upon the spectrum, chiefly used a round hole instead of a slit, and found that he could improve the spectrum by making the aforesaid aperture smaller; when the hole was too large, he found that the colours overlapped each other, but that as he diminished the orifice, the colours became purer and well separated. The lecturer illustrated this by passing white light through one glass trough containing an infusion of litmus which cut off the yellow rays, then through a trough containing solution of bichromate of potash, which cut off the blue and violet rays, so that pure red and green light could alone pass through the two solutions. A rotating diaphragm, as used in photographic lenses, was placed in the path of the rays; with large apertures the red and green images of the orifices were seen overlapping on the screen; he then rotated the diaphragm until with the smaller apertures the red and green rays were well separated. With the larger apertures, the colour of the space where the red and green rays overlapped was orange, proving that a visual orange can be made by mixing pure red and green lights.

Considering the great reputation of Sir Isaac Newton, Lord Rayleigh thought it to be strange that so few persons had studied the solitary book on *Optics* which had been written by that philosopher; it contained information on some points which in more modern times had been brought forward as novel. That Newton knew that a slit could be used in a spectroscopic as well as a hole, was proved by his statement that an "elongated parallelogram" would answer the same purpose; the lecturer supposed that the novelty of any more modern device did not consist in the substitution of the word "slit." An argument had been raised that if Newton had used the slit, he must have discovered Fraunhofer's lines, but in Newton's days there was great difficulty in getting good prisms, and there was at that time no reason why any one should suspect the existence of the lines; nevertheless, it was rather strange he did not discover them. At all events, it is certain that he used a slit. Wollaston was the first person who saw the lines; Fraunhofer, the optician, afterwards made an elaborate study of them, and they have ever since been known as "Fraunhofer's lines." The study of those lines has since become almost a special branch of science, so that it now requires the

labour of years for the student to become well acquainted with all that is known about them.

Herschel formed his spectrum very much in Newton's manner; after throwing it upon a screen he introduced into it a thermometer, and tested the heating power of the different rays; he found little warmth in the blue and green, more in the yellow and red, and more still in the dark region beyond the red. Dr. Thomas Young, in lecturing upon light before the Royal Institution, in 1807, characterised this discovery of Herschel's as one of the greatest which had been made since the days of Newton, and so, said Lord Rayleigh, it was. Subsequently more delicate instruments were used to measure the heat of the rays of the spectrum, and the first to use the thermo-electric pile for the purpose was Melloni. The lecturer here threw a spectrum upon the screen and moved a thermo pile in front of the screen; the terminals of the pile were connected by wires with a reflecting galvanometer, which threw a disc of light upon a white scale several feet long; as the pile was moved along the spectrum, the galvanometer needle indicator began to move as the yellow rays were approached, then proved more bent to exist in the red, and finally gave the greatest deflection in the invisible region beyond the red.

Herschel in his earlier papers inclined to the modern view, that there is very little difference between heat and light, but undoubtedly in his later paper he sums up against that view, and concludes that two agents are at work in the spectrum. He argued that if by any means it were possible to alter the proportion of the two effects two agents must be at work, and he found that by passing red rays through red glass very little difference was produced in the amount of light transmitted, but a great difference in the amount of heat, hence he came to the conclusion of the existence of two agents. His conclusions, however, were not accepted by his contemporaries; they were opposed by Young, who argued that the rays of the spectrum were but different degrees of the same scale, and that the apparent difference between radiant light and radiant heat is more in our sensations than in the things themselves. He argued that the longer waves might produce the sensation of heat, and the shorter waves of light darken emulsions of silver, and otherwise excite chemical action. The latter view is the one now generally accepted, except that it is now known that the rays which excite chemical action vary with the substances upon which those rays fall. Professor Langley, of America, has published that Draper, in comparatively recent times, first promulgated this view, but Lord Rayleigh said that it was a serious misrepresentation of the history of the subject. Long before Draper's utterance on the subject, the view that light and heat are at root much the same thing had been generally accepted in this country; he (the speaker) had been taught it before Draper wrote about it, and the view had been promulgated in earlier times by Dr. Balfour Stewart and others in this country. Here Lord Rayleigh projected a spectrum upon what he said was known to photographers as "bromide paper;" some pyro and ammonia developer was then painted over it by an assistant, and a vigorous image came out where the blue and violet rays fell. Herschel, he said, experimented with many substances, including bromide of silver, which he found could, by sufficient exposure, be impressed down into the red of the spectrum; these experiments were performed in 1840-50. It was once believed that steel could be magnetised by certain rays of the spectrum; he (the lecturer) thought this to be an error, demonstrable by proper performance of the experiments. Against Herschel's experiment on the differential action of red glass there is nothing but theory; if Herschel is right modern theories of light are wrong, or want revolutionary remodelling. He (Lord Rayleigh) believed that if Herschel's experiment were properly performed, and all conditions taken into account, Herschel would certainly be proved to be in error; it might be well if some of the persons, such as those who write text books, would settle this point by experiment, that the modern view may not rest upon accepted theories alone, but those theories are so strong and so well supported by proved facts, that he did not expect the substantiation of Herschel's view, the acceptance of which would shake the wave theory of light to its foundation. W. H. HARRISON.

PARIS EXHIBITION REGULATIONS FOR PHOTOGRAPHERS.

A copy of the full text of the rules relating to photographing in the coming Paris Exhibition has been sent to me. The rules are signed by M. G. Berger, Director-General of the Exhibition, and by the Commissioner-General, M. Lucien Pautreaux, Minister of Commerce and Industry. My translation of the said regulations runs as follows:—

ARTICLE FIRST.—The right to take photographic views in the Universal Exhibition of 1889 will not be made the object of any monopoly or exclusive privilege. All photographers permitted, on application, to take pictures within the Exhibition limits, and upon the days and hours fixed by the Administration, must be provided with an authorisation, signed by the Director-General of the "Exploitation." For that which concerns the Fine Arts group (classes one to five) the authorisations must be signed both by the Fine Arts Director, and by the Director-General of the Exploitation.

ARTICLE SECOND.—Photographers authorised, under Article I of the present regulation, will work at fixed times. For each of these admissions a payment of twenty francs (sixteen shillings), to go to the Administration, must be made for each apparatus employed. This payment must be made and receipted in the cashier's office at the Exhibition.

The admissions will have a duration of four hours; either from eight in the morning until midday, or from ten in the morning until two in the afternoon. All authorisations will be valid only for the days and hours indicated. The Director-General of the Exploitation will always have the power of renewing them, without additional payment, if they have not been used on the days and hours fixed.

ARTICLE THIRD.—Applications for authorisations addressed to the Director-General of the Exploitation must state:—1. The number of assistants the applicant intends to employ. 2. A statement of what apparatus he intends to use. 3. A formal declaration that the applicant takes the whole responsibility of any consequences his reproductions may entail. 4. An undertaking to conform to the police regulations and the rules of the interior.

ARTICLE FOURTH.—Season tickets at the price of 300 francs for each piece of apparatus employed, available during the whole term of the Exhibition, at the hours fixed by Article 2, will be issued to those photographers who apply for them.

ARTICLE FIFTH.—Assistant operators, like the operators themselves, must pay the same entrance fee as ordinary visitors, in addition to the sum paid for authority to photograph.

ARTICLE SIXTH.—Operators admitted to photograph must not, under any circumstances, introduce within the Exhibition fire, or explosive or inflammable substances. Their preparations must be made outside the limits of the Exhibition.

ARTICLE SEVENTH.—All reproduction of objects exposed, whatsoever be the nature of the said objects, is absolutely subject to permission being given by the exhibitors thereof or their authorised agents, countersigned by the Director-General of the Exploitation.

ARTICLE EIGHTH.—Photographers furnished with authorisations have the right to take general views of the palace, parks, and galleries, on condition that they send ten proofs of each view to the Administration.

The above is the last of the conditions laid down in the official regulations relating to photographing inside the Paris Exhibition.

W. H. HARRISON.

CAMERA CLUB CONFERENCE, 1889.

THE 1889 Conference will be held in the theatre of the Society of Arts (by kind permission of the Council) on Tuesday and Wednesday, March 26 and 27, under the Presidency of Captain W. de W. Ahney, C.B., R.E., F.R.S.

PROGRAMME.

Monday, March 25, at 8 p.m.—Smoking Concert at the Camera Club Rooms, 21, Bedford-street, W.C.

Tuesday, March 26.—Conference and Exhibition of Apparatus at the Society of Arts, 18, John-street, Adelphi, to be opened by the President at 2 p.m. Papers to be read from 2 p.m. to 5.30 p.m. in the theatre: Mr. Conrad Beck, *Depth of Focus*; Mr. J. Brett, A.R.A., *The Relation of Photography to the Pictorial Art*; Mr. P. H. Emerson, B.A., M.B., *Science and Art*; Mr. Lyonel Clark, *A Comparison of Developers*; Captain W. de W. Ahney, C.B., R.E., F.R.S., *The Law of Error and Photography*; Mr. T. H. Dallmeyer, *Shutters*; Mr. G. Lindsay Johnson, M.A., M.B., *A Shutter Speed Measurer*.

At 8 p.m.—Exhibition of Lantern Slides in the theatre. Slides from Paris, Vienna, American, and English Societies.

Wednesday, March 27, 10 a.m.—Apparatus on view at the Society of Arts, and Exhibition of Photographs by Members at the Club Rooms, 21, Bedford-street.

2 p.m.—Renewal of Conference in the theatre, Society of Arts. Papers to be read from 2 p.m. to 5.30 p.m.: Mr. C. H. Bothamley, *Chemical Changes from the Modern Point of View*; Mr. A. A. Common, F.R.S., *Irradiation in Astronomical Photography*; Mr. A. Dawson, *The Field of Photography*; Mr. W. T. Wilkinson, *Dry Plates for Photo-litho and for Collotype*; Mr. A. Pringle, *Photo-micrography*; Captain A. M. Mantell, R.E., *Photography applied to Military Purposes*.

7.30 p.m.—Annual Club Dinner for Members and friends at Holborn Restaurant.

All photographers are cordially invited to the Conference and Exhibitions. The meetings (except the smoking concert) will be open to ladies.

G. DAVISON, } Hon. Secs.
E. G. SPIERS, }

Camera Club, 21, Bedford-street, Covent-garden, London, W.C.

PATENTS COMPLETED.

IMPROVEMENTS IN FRAMES OR STANDS FOR HOLDING PHOTOGRAPHIC AND OTHER PICTURES AND TABLETS.

No. 3115. JOEL CADDURY, Great Hampton-street, Birmingham, in the County of Warwick, and WILLIAM HENRY RICHARDS, Long-street, Sparkbrook, Birmingham.—*March 1, 1888.*

THIS invention relates to what are known as frameless photographic holders, consisting essentially of a back provided with certain fittings and spring and other clips which embrace and secure the glasses, with a photograph or other picture thereunder to the said back framing, which is made of wood, *papier maché*, or other solid substance.

This invention has for its object the securing of the said fittings, clips, and the like to the backs, as hereinafter described, by which improvements the method of attachment is greatly simplified and the appearance of the article greatly improved.

Hitherto, the spring and other attachments and fittings have been secure to the wood backs, commonly employed, by rivetings.

According to our invention, the said fittings are attached by ears or spike-like extensions made in one piece with the metal of the said fittings and passed through piercings in the said backs, and clenched or turned down upon the inner side.

In carrying out our invention we will describe it in connexion with fittings for photographic and other frames, as described in application for Letters Patent made by us on the 25th day of November, 1887, and numbered 16212.

To form the rest, which comes at the lower back part of the frame, we take a blank of sheet metal, making, as it were, a bar with ear-like extensions at its two opposite ends, which are turned inwardly at right angles to the other part.

The underside edge of the bar is provided at its two opposite ends with extensions, which are bent forward under the bottom edge of the frame like claw rests, upon which the lower edge of a photograph or other picture and the covering glass is supported.

The ears or spike-like extensions, bent from the extreme outer ends of the bar, are passed from back to front through longitudinal piercings made through the back, and with the extreme ends of the said ears bent flat to the plane of the front face of the said back.

The spring clip, which consists of two flat bars sliding one upon the other, with a spring interposed between a shoulder of one of them, and an abutment formed by the cutting away of the back part, wherein a portion of the said clip lies, is secured by the under-bar having ears or prong-like extensions at the upper and lower ends, which pass through like piercings made through the said wood—back part—and then clenched or turned down upon the front face.

The movable bar has a cross pusher bar at its lower end, and a hook-like claw at its upper end.

Thus the fittings are secured in their respective positions by ears or prong-like extensions which pass through piercings in the wood or other back and then clenched.

AN IMPROVED PHOTOGRAPHIC CAMERA AND CHANGING BOX COMBINED.

No. 4149. WILLIAM A. BRICE, Genova, Italy.—*March 17, 1888.*

MY invention consists in a photographic camera so constructed as to have two chambers, in one of which is stocked a pile of sensitive plates sufficient to fill it, the other being an exposing chamber. These are separated by two thin partitions, capable each of being moved upwards and downwards to a limited extent by means of small knobs or handles on the outside. By the action of these the upper plate of the pile can be transferred to the empty exposing chamber and dropped to its rear, where it is securely held conjointly by the pressure against one of the partitions aforementioned and that of a hinged flap, both being operated from the outside. This hinged flap serves the double purpose of conveying the sensitive plate or film gently from the upper opening through the empty space of the operating chamber by acting as an inclined plane whereby the plate, paper, card, or other sensitive film is ultimately conducted into accurate position at the point of focus, and also of acting as a movable abutment on one side against which the plate or other sensitive film is pressed by a spring stud underneath so as to ensure accurate register of focus. On releasing the plate from pressure after exposure, this plate, now impressed with a latent image, may be slid into and at the bottom of the stock chamber, the upper one of the series of plates being by like means slid over the top of the partition and made to take the place of the one removed at the focussing plane in the exposing chamber; and so on in rotation.

It is fitted with a finder, and the lens is covered by a shutter which may be operated either instantaneously or as slowly as may be desired. Suitable arrangements are provided for focussing.

After the chamber has been filled with sensitive plates, all the operations of transferring and exposing them are made without the camera being again opened. The final specification is illustrated.

LANTERN SLIDE COMPETITIONS.—Prizes in the competition instituted by S. Fry & Co., Limited, have been awarded as follows: 1st, E. Brightman, Bristol; 2nd, J. Mure, Paisley; 3rd, A. R. Dresser, Bexley Heath; 4th, W. Norgrove, Bristol; 5th, J. W. Shores, Bridlington Quay; 6th, W. H. Bailey, Cuckham. Nearly five hundred slides, from upwards of eighty competitors were sent for competition, and Mr. Hepworth (the Judge) expressed his admiration at the high order of excellence displayed, rendering the final selection a matter of extreme difficulty. Three out of the six successful competitors employed hydroquinone as a developer.

IN the slide competition of F. W. Vétel & Co. the following are the successful competitors:—1st prize of 3*l.*: Mr. G. I. T. Walford, 10 Soames-street, Denmark-park, London; 2nd prize of 1*l.* 10*s.*: W. F. Mackenzie, Lenzie; 3rd prize of 15*s.*: Mr. W. Marsden, 26 Sefton-street, Southport; 4th prize of one gross lantern plates: Mr. J. Huff, 10 Victoria-road, Penrith; 5th prize of half gross lantern plates: Mr. T. Harriman, Henley-on-Thames; 6th prize of half gross lantern plates: Dr. R. Atkins, Watford.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

LAST Tuesday night, at a meeting of the above Society, held at 5a, Pall Mall East, London, Mr. Thomas Bolas presided.

Mr. ARNOLD SPILLER said that five years ago he developed half a dozen negatives with quinol, and they were more stained than any he had developed in his life; perhaps the sample was bad.

Mr. A. COWAN thought that it had been proved that quinol would equal pyro as a developer; perhaps it gave less stain.

Mr. LOUIS MONTEFIORE believed that quinol gave good results with the more certainty; it always gave him fairly printable negatives, and he had not the same certainty with pyro; the former salt allowed greater latitude of exposure.

Mr. NEWLAN had used quinol for five years, and never had a bad negative with it.

Mr. CHAPMAN JONES had found some samples of commercial plates which would develop well with pyro, and not at all with quinol.

Mr. W. E. DEBENHAM, unlike some experimenters, had found that he could not use the quinol solution again and again, because it so lengthened development.

Mr. WINTER recapitulated some of Mr. Swan's results, and exhibited his experimental negatives.

Mr. COWAN thought that one of the pyro negatives before them, showing slight green fog, would print better than a quinol-developed negative before them, showing slight grey fog.

Mr. MONTEFIORE had found quinol to work well with meta-bisulphite of potash, but the developer required more alkali to neutralise the excess of sulphurous acid; caustic alkalies, instead of carbonates, reduced the time of development.

The CHAIRMAN remarked that Mr. Montefiore's negatives exhibited the slight veil often sought after.

Mr. MONTEFIORE preferred the slight veil.

Mr. WINTER said that Mr. Swan had found four grains of meta-bisulphite to one of quinol to stop development.

Mr. W. BEDFORD remarked that Mr. Swan had found sulphite of soda to be a strong restrainer, so perhaps it was hardly fair to compare quinol so used with pyro used without sulphite. He thought the opinion of the meeting should be taken on Mr. Swan's suggestion of using the shorter word "quinol" in place of "hydroquinone" in photographic circles.

The CHAIRMAN put this to the vote, and declared the majority to be in favour of "quinol."

Mr. W. B. HARRISON believed that Mr. Francis Cobb had first used the word "quinol" in photographic literature, in one of the almanacs a year or two ago.

Mr. GUTZ had found quinol and pyro to give the same results; quinol acted quickly towards the close of the development, and the plate had to be removed at just the right moment, or there would be too much density; he had had strong green fog with it.

The CHAIRMAN asked if lime in the water made any difference with quinol?

Mr. NEWLAN sometimes used well-water, rich in lime, and found that it made no difference. Quinol stained if plates were put in the hypo without washing, and when there was no sulphite in the developer.

Mr. BEDFORD had developed paper bromide prints with it, and put them direct in the hypo without getting stains, except with one sample of paper.

Mr. HERBERT FRY had found the slightest washing to answer, and no acid bath necessary.

Mr. J. J. BRIGGS had seen prints bearing out that statement.

The CHAIRMAN suggested that the kind of gelatine used might have an influence.

Mr. SPILLER said that that was Mr. W. K. Burton's opinion.

Mr. J. D. ENGLAND stated that the coarser the bromide in the gelatine, the greater was the liability to stain.

Dr. LINDSAY JOHNSON wished to know if quinol would work as well as pyro where there were violent contrasts, as in dark rock foregrounds with snow-clad mountains behind. He had been doing this class of work in Switzerland, and found that by taking Captain Abney's advice, and using very little pyro, much restraining bromide, and long development, he got on very well.

Mr. COWAN responded that some of the negatives on the table proved that quinol gave great latitude.

Mr. MONTEFIORE had found that under-exposed and over-exposed negatives could be developed well with quinol in the same solution.

Dr. JOHNSON had modified commercial rocking apparatus to keep a large dish rocking during long developments.

Mr. J. HERBERT asked if quinol would give as delicate half-tones as pyro?

Mr. WILLIAM ENGLAND exhibited two flash lamps he had made for a shilling each of tin and pieces of gas tubing; by branch tubes he could fire off the two

of them at once and release the shutter pneumatically. He then took two flash-light pictures of the meeting.

The CHAIRMAN announced that Dr. Lindsay Johnson would give ten guineas to the Society towards founding a museum if other members felt sufficient interest in the matter to subscribe a like amount. He (the Chairman) had no doubt that other members would subscribe more than ten guineas, and as the Society had no premises of its own, the objects collected might be temporarily deposited at South Kensington.

Mr. ARNOLD SPILLER thought it good to have a museum, but doubted if it would be well to join the South Kensington clique.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

ON Thursday, last week, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. H. M. Hastings presided.

Mr. F. W. Pask was elected a member of the Association.

Mr. A. HADDOX asked how an American firm registered the speed of films which they advertised as giving twenty-seven on the sensitometer. Warnerke's sensitometer only registered up to twenty-five, and without the firm stating what sensitometer was meant the information was useless to every one.

There was no reply.

Mr. J. B. B. WELLINGTON exhibited two prints made by General Dawson on Eastman's bromide paper, the one developed with ferrous oxalate and the other with quinol; the latter was the better of the two. This experience, he said, did not agree with that of Messrs. Morgan & Kidd, who had tried quinol for enlargements and found it to give defective results on the edges of the high lights.

The HON. SECRETARY announced that on that day fortnight, March 7, the lantern slides competitively printed by various members from negatives of intentionally varied quality would be exhibited and the decision of those present taken as to the best results.

Mr. A. HADDOX then gave an address and made some experiments relating to explosives. Some of the most explosive variety of gun-cotton he placed in alcohol and ether, and throughout the evening it would not dissolve; he then took it out and substituted some photographic pyroxyline, which dissolved immediately; the explosive sample was next dried and fired off to prove it to have been gun-cotton. He summarised the results of the researches of Hadow and others as to the nature of varieties of pyroxyline, and hammered upon an anvil a piece of paper which had been nitrated; it exploded only where the blow fell; the ignition did not spread outside. He said that Mr. Hubert's way of making a flashing magnesium light was highly dangerous, because any uninformed person using it might be tempted to reduce the size of the glass chamber to economise weight, and the extra confinement of the gun-cotton might lead to a violent explosion. In illustration of this, he placed a small tuft of gun-cotton in a glass flask, and, after placing both in a packing case and getting the Chairman to stand on the top of it to keep the case down, he fired the gun-cotton by means of a fine platinum wire ignited by electricity. There was a violent explosion inside the box. He then dusted some fulminate of mercury over a glass plate and fired the fulminate, which went off with a flash and left the plate silvered all over, so as to make a passably good mirror. He stated the conditions under which gun-cotton would and would not ignite, and explained how in warfare it is fired by means of detonating fuses.

The HON. SECRETARY remarked that those members of the Association who were not present that evening had missed a great treat.

Mr. HADDOX then exhibited an annulus of glass which he had cleanly cut from a glass tube by making a diamond cut upon the inside of the tube; had the cut been made outside, he said, no ring could have been cut out.

CAMERA CLUB.

ON Thursday, February 21, a discussion on *Films* was opened by the reading of communications upon various branches of the subject from Mr. H. H. O'Farrell (in India), Mr. H. Tolley, and Mr. George Mansfield. Sir George Prescott occupied the chair.

Mr. O'Farrell's paper referred to the Froedman films and to methods of keeping stripping films.

Mr. Tolley wrote concerning oiled paper negatives and strippers, and he sent some superb specimens of the negatives from which prints then upon the walls of the Club were taken.

Mr. Mansfield forwarded excellent work upon the new celluloid films of Messrs. Carbutt, and gave particulars of exposure and treatment.

The Hon. Secretary also showed negatives made on Allen & Rowell's ivory films (celluloid), and a long and interesting discussion was taken part in by Captain Barnes, Messrs. Davison, Walker, Bellsmith, Robinson, Lyonel Clark, Sage, Shipton, Paterson, S. Bourne, and Elder.

On Thursday, March 7, Mr. W. Adcock will read a paper entitled *Aims*.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

THE annual meeting of this Society was held at the Committee Rooms, 181, Aldergate-street, E.C., last Friday, the 22nd ultimo, there being a good attendance.

From the Secretary's report, which was read, it appears that the total disbursements for the year have been 74*l.* 14*s.* 6*d.*, against total receipts, 109*l.* 15*s.* 10*d.*, showing an increase of 35*l.* 1*s.* 4*d.* on the year's transactions. The fund has, therefore, been raised from 273*l.* 6*s.* 6*d.* to 308*l.* 7*s.* 10*d.*

The election of officers for the ensuing year then took place.—*President*: Mr. J. Traill Taylor.—*Trustees*: Captain Abney and Mr. W. S. Bird.—*Treasurer*: Mr. John Stuart.—*Secretary*: Mr. H. Harland.—*Auditors*: Mr. J. S. Rolph and A. Mackle.—*Committee*: Messrs. W. Bedford (Chairman), T. J. Collins (Deputy), H. D. Atkinson, W. F. Benham, F. H. Berry, T. Bolas, J. J. Briggs, H. E. Clifton, T. E. Freshwater, W. J. B. Humphreys, H. J. White, and J. Zaehnsdorf. (The Committee, in accordance with powers with which they are invested, afterwards added to their number Mr. F. W. Cox.)

NORTH LONDON PHOTOGRAPHIC SOCIETY.

An ordinary meeting was held on February 19, at Myddelton Hall, Islington, — Mr. J. Traill Taylor, President, in the chair.

Mr. JAMES MARTIN presented to the Society a fine platinotype print of the President. He then called attention to the discolouration of the paper of a platinotype print which had been framed about two years—the part protected by the rabbit of the frame remaining unchanged.

The CHAIRMAN explained that the same effect was noticed some years back in carbon prints, which were thought to have faded; investigation, however, showed that the paper alone had become discoloured by exposure to light and atmosphere, but the print itself remained unchanged.

Mr. F. W. HART said that the discolouration of the paper was greatly influenced by the way in which it was framed. To properly protect a print, the glass should be pasted into the frame with pieces of card all round, the mounted print laid down, and the backboard fastened in and pasted round. He considered the discolouration to have been caused by fine dust and smoke getting in round the glass and settling in a fine film on the surface of the print.

Mr. E. CLIFTON said that paper made of wood pulp and bleached returns to its yellow colour when exposed to light; pure flax paper will not turn yellow when exposed to light. He had fastened a line negative on a clean board and exposed it to the light, the result was yellow lines on a white ground; he, however, considered the discolouration of the print in question to have been caused by smoke or dust settling on it.

Mr. CLIFTON had noticed a way of sealing up an engraving; the print was damped and the edges turned over and pasted on to the front surface of the glass; when dry the print was strained tightly over the glass, and the back-board pasted in.

Rev. E. Healy showed a shutter by Newman for moderately short or time exposures; it worked with an up-and-down motion.

Mr. HART exhibited an interesting 12 x 10 group taken by the London Stereoscopic Company on the occasion of the Jubilee dinner of the Union Bank of London, the Hart and Bishop lamp being the illuminant employed. Fifteen lamps, each burning five grains of magnesium, were used, and a fully exposed negative of a group of over seventy persons was obtained. Four such groups were taken, the whole time occupied in focussing, charging the lamps, &c., being only a few minutes. As a proof of the extraordinary power of the light, it was mentioned that an old Ross' doublet lens working at $f=24$ was used, the light being twenty-seven feet distant from the sitters.

Mr. HART then gave a demonstration connected with flames. He said:—

In the production of flame our starting-point shall be hydrogen. So far as we know it is a simple element; our accumulated experience, by which we test all theory, takes us no further at present. When I first began to study the nature and properties of flame, hydrogen was said to be a permanently elastic gas, our experience knew no more; since then it has been proved by experiment that hydrogen can be liquefied. See what a valuable thing experience is; it protects us in every direction, it enables us to devise new combinations for experiments, which are the buds of experience, likely to develop into a fresh limb of the tree of knowledge. The first experiment I show just comes within the range of the Victorian age. Here I have an ordinary Bunsen burner: turn off the air from entering below, and the luminous flame appears; I introduce a piece of tube, and you see that I draw off gas which is alight at the other end; this proves that that kind of flame at least contains gas ready to ignite so soon as it can find oxygen to combine with, and, inasmuch as magnesium also demands oxygen for its combustion, it is injudicious to allow the magnesium to be robbed of oxygen by discharging it into a gas already in the most favourable position to combine with oxygen. The gas is issuing at a very small pressure at the top of this tube, and when I turn on the air and convert the luminous into a non-luminous, or Bunsen flame, the pressure is still less at the end of the tube where the gas and air are burning as a mixture; it is still short of its full complement of oxygen, which has to be made up by the air outside to complete perfect combustion of the gas in this form of burner. When I reduce the quantity of gas to a portion so near its theoretical quantity entering the air holes, the flame at the top of the tube will be so exceedingly unstable that it becomes an explosive mixture issuing under slight pressure, and, consequently, will fire down, as you see; so to make it a practical Bunsen flame we must leave a little excess of gas in the mixture for the outside air or oxygen to combine with. I now introduce the tube about an inch above the orifice of the burner, and you see a portion of the mixture of gas and air is drawn off alight at the other end of this tube, and although this flame is permanent for many purposes of the chemist, it is easily put out, as you see, when I send a puff of air, such as used for ejecting magnesium powder, up through the tube. The small air tube would have to extend to above the mouth of the gas tube to be able to use it all. In all cases, whether of spirit or gas, luminous or non-luminous, I employ double flames to produce a homogeneous flame, through which to eject the magnesium. Here is another experiment to show that the large spirit flames employed for igniting the powder are flameless in the centre from absence of oxygen. Here is a tray packed with cotton waste saturated with spirit, in the centre I place a small metal tray containing a night light—there it is burning brightly; now, on igniting the spirit you see that it goes out from loss of oxygen, the interior of that flame is hydrocarbon vapour, most eager to combine with more oxygen than it already contains, so as to form carbolic acid with the carbon; so here we have two elements—hydrogen and carbon, both of which would rob the magnesium of oxygen under the circumstances, such as passing it through the flame.

A brief discussion took place upon this subject.

The next meeting will be on March 5, which will be the annual exhibition.

WEST LONDON PHOTOGRAPHIC SOCIETY.

An ordinary meeting of this Society was held on Friday, the 22nd inst., the President in the chair.

Mr. T. STAFFORD HAZEON read a paper on 'The Autotype Process,' with practical demonstrations. He prefaced the practical portion of his paper by giving a brief history of the process. He considered autotype had strong claims on the amateur for support on account of its simplicity, the range of colours obtainable, and, more important still, by reason of its absolute permanency. A vigorous negative gave the best results—those developed with hydro-

quinone were specially suitable. Ordinary negatives required treating by the double transfer process, therefore it was better to make a reversed negative; a simple mode of doing this in the case of landscapes and portraits was to expose the plate with the glass side next the lens—of course all patches of emulsion must be removed from the back of the plate. The focussing screen also would require readjustment. In autotype printing no image was visible before development, and in order to judge the proper amount of printing, an instrument called an actinometer had to be employed. The ready sensitised tissue as sold by the Autotype Company was about the rapidity of silver paper, but that sensitised by himself was much quicker. The operation of sensitising was very simple, and consisted in soaking the pigmented tissue in a bath consisting of one ounce of bichromate of potassium dissolved in twenty ounces of water. The tissue is allowed to soak for three minutes, taken out, squeezed, and put on a piece of blotting paper, and allowed to dry. The lecturer particularly recommended the process for the production of lantern slides; it produced a beautiful result, very free from grain. The print, after exposure, is developed by immersion in water at a temperature of about 110° Fahr. After development it is placed in an alum bath, and a final rinse in cold water completes the operation. Mr. Hazeon then gave a practical demonstration of the development of the exposed tissue by the single transfer process, the temporary support, pictures on opal and on glass, and concluded by remarking that expensive apparatus was by no means essential to work the process. Although he had a lot of paraphernalia with him, when at home he developed small prints in an ordinary basin and large ones in the sink of his dark room. All the necessary apparatus would be in every amateur's possession.

A large number of very fine prints in autotype, and also the dishes and apparatus necessary for the demonstration, were lent by the Autotype Company for the occasion.

Mr. DELVES BROUGHTON suggested that the over exposure might be due to the continuing action of light.

Mr. HAZEON had not noticed the effect referred to.

Mr. E. W. FOXLEE had had considerable experience in working the autotype process. Continuing action had been observed by early workers in the autotype process, including Mr. Swan, but eminent French authorities had denied that any such action occurred, and some years ago Captain Abney read a paper on the subject before the Photographic Society. At that time the nature of the action was found to be uncertain. Sometimes it would go on more rapidly in six hours than it would at other times in twenty-four. He (Mr. Foxlee) then took the matter up and made numerous experiments, and discovered that in damp and foggy weather the action was rapid, while in dry weather it was almost nil. He came to the conclusion that the phenomenon was due to the presence of moisture; if moisture were entirely absent from the tissue no action would go on. To prove this he made a number of exposures of equal duration from the same negative. Some of these he sealed up in an air-tight case. After a hundred days no further action was noticeable. Upon development the remaining prints were allowed to remain exposed to the atmosphere for varying periods of time, and showed signs of over exposure in proportion to the length of time they had been allowed to absorb moisture from the air. Those and other prints he had exhibited at the Inventions Exhibition and had received a medal for them. He did not agree that it was best to buy the tissue ready sensitised. The operation was an easy one, and if done at home the tissue could be prepared to suit the negatives. A thin negative required a tissue lightly sensitised, and a hard negative wanted a tissue very strongly sensitised to get the best result. He preferred to sensitise large sheets cut across the band. The dish should be the width of the paper, which should be rolled up, allowed to uncoil, and gradually drawn over the solution. A couple of glass rods placed across the dish facilitated the operation of draining the tissue and removed the surplus solution from both back and front.

Mr. HAZEON had found some colours to print more quickly than others.

Mr. FOXLEE: It depended upon the solubility of the pigment employed. Blue, for instance, was more soluble than red.

Mr. WHITING said the actinometer which had been exhibited, although simple, was not very perfect in its action. Light had a greater effect upon it than it had on a dense negative, and it required to be very carefully watched. He had brought with him an actinometer constructed of a series of thicknesses of coloured collodion. You put all your frames out together when No. 5 appeared on the paper, you turned down the frames which required that exposure, and so on with the remainder. There was then no trouble in changing and watching the tints.

Mr. WALTER COLLS had found the addition of a few drops of glycerine to the sensitising bath an improvement in hot weather. It prevented the tissue getting bad.

Mr. FOXLEE strongly deprecated the use of glycerine in such a climate as England. It would greatly promote the continuing action.

Mr. J. A. HODGES wished to draw attention to the fact that the working of the autotype process was attended with some risk. He thought beginners should be warned not to dabble too much in the sensitising solutions, in order to avoid the danger of contracting what was known as the "bichromate disease." He would ask Mr. Foxlee whether any effective precautions could be taken, and whether the malady affected all persons alike.

Mr. HAZEON said not one in a hundred was affected. If he were attacked he would discontinue working the process.

Mr. FOXLEE had suffered severely. His case had been exhibited before the medical society. However, he did not think the amateur need, with ordinary care, anticipate danger. He could bring out the disease in two hours. He attributed his own attack to gross carelessness. The disease attacked about half the employees at the Autotype Works. Buying the tissue sensitised did not obviate the danger which lay in the process of developing. If injury resulted from sensitising the tissue, it was owing to the bichromate getting into an abrasion of the skin, which produced a different effect to that known as the bichromate disease.

The PRESIDENT inquired whether the continuing action Mr. Foxlee had referred to had been utilised commercially.

Mr. FOXLEE replied that it had very extensively. It was used first by the

War Office authorities at Woolwich, and later at the Autotype Works, particularly during dull weather, when a large number of prints had to be got off. They were only half exposed, were then placed in a damp situation, and kept the necessary time before development.

The next meeting, on March 8, is a lantern night, when Mr. G. F. Blackmore will describe a new method of toning lantern slides. Visitors invited.

WEST KENT AMATEUR PHOTOGRAPHIC SOCIETY.

At the usual fortnightly meeting, held in the Institute, Bexley, on Friday, the 22nd instant, Mr. Fringla presided.

Mr. DRESSER showed a number of bromide prints of local frost-and-snow scenes. Some time since, he (Mr. Dresser) advocated a novel competition; instead of giving medals for one or two prints, give each competitor twenty-four sheets of paper and award the prize to the competitor who had the best average; out of the twenty-four pieces he himself had obtained twenty-three perfect prints.

A negative of a snow scene was then handed round by the Secretary. It was marked all over by a sort of granular appearance; various causes were assigned for this, but the conclusion arrived at was that the markings would not interfere with the printing qualities of the plate.

Mr. PRINGLE called attention to a feature of this negative which was well known to old photographers but had not had the attention it deserved until Mr. Warnerke took it up; he referred to the relief of the image.

It was stated by one of the members that if a negative was dried with spirit and heated in the drying, this relief was very prominent.

A negative was shown by Mr. Edwards which had a broad band of discolouration at the bottom. In the discussion it was stated that either the hypo had not been properly washed out or that it was insufficiently fixed.

Mr. PRINGLE then exhibited the members' slides in the lantern. As each appeared upon the screen he pointed out the defects and good points in each, also giving hints for the remedy of the former. He advocated a warm colour for landscape slides, and showed the members some examples of colour and density for their guidance.

During the display a running fire of criticism and discussion was kept up by the various members. There was also an informal discussion after the exhibition.

The next meeting will be held in the Board Room, Bexley, Friday, March 8, upon which occasion an address upon *Lantern Slide Making* will be delivered by Mr. Charles Huxey.

CHILTENHAM PHOTOGRAPHIC SOCIETY.

On the 19th instant this Society had a lantern night at the Assembly Rooms as well as an exhibition of photographs taken by members. There was a large attendance. The pictures exhibited, chiefly landscapes and studies taken during the recent frost and snow, were mostly printed in platinum or on bromide paper, albumenized paper being evidently out of favour with the amateurs, especially for large work.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

THE members of this Society were favoured on Wednesday evening with an interesting lecture by Mr. JOHN STORRIE, the Curator of the Cardiff Museum, on his recent discoveries at Llantwit-Major of Roman remains. The lecture was profusely illustrated by limelight. A full account of researches in this district will shortly be placed before the public in pamphlet form, and may be photographically illustrated. It will prove a welcome addition to the antiquarian literature of Glamorganshire.

The next meeting of the Society will be on March 6, when Mr. W. Windsor will give a lecture on *The Lantern and How to Work It*.

EDINBURGH PHOTOGRAPHIC SOCIETY.

THE third ordinary meeting was held in the Front Saloon, 29, George-street, on Wednesday evening, January 9, 1889. In the absence of the President, Mr. H. J. Blanc, F.S.A.Scot., Mr. W. T. Bashford, Vice-President, occupied the chair.

The CHAIRMAN intimated the receipt by the Secretary of a note from Mr. Hume, in which he regretted that he was unavoidably compelled to be absent from his post.

It was next explained that the Secretary, who had been requested by Mr. Bell-Smith to invite the Edinburgh Photographic Club and the Leith Amateur Photographic Association to a demonstration which Mr. Bell-Smith had volunteered for the ensuing meeting, was anxious to have the authority of the Society as a necessary preliminary to his taking any steps in the matter. The requisite consent was very freely given.

Introducing the notice of motion given by Mr. John M'Kean at the December meeting, the CHAIRMAN stated that, as the last issue of the laws was almost exhausted, the Council were desirous that, before requiring the assistance of the printer, these laws should be thoroughly overhauled, and, subject to the approval of the Society, be recast in a more consecutive form. Mr. M'Kean, relinquishing his own original motion, formally moved the adoption of the course proposed by the Council, whereupon it was agreed that the latter were at an early date to remodel the laws and submit a draft to a general meeting of the Society.

On the suggestion of Mr. HUME, who specially wished discussion to follow his own remarks, the next item of business was replaced by the exhibition by Mr. Fergus of Caldwell's instantaneous shutter, made by Mr. William Wray, optician, Highgate-hill, London. This shutter works with a rapidity from two seconds up to the one-fourth-hundredth part of a second, and it may be set to any intermediate time. It opens and shuts from the centre, is worked by a pneumatic attachment, and has this peculiarity, that although placed between the lenses it does not interfere in the least with the usual stops, or even with the iris diaphragm, should the lens possess one. The vibration which usually

accompanies such shutters appears in the Caldwell shutter to be entirely eliminated, and as it is placed between the stops and the cap combination of a rectilinear, it is in the very best position to obviate vibration. The shutter is beautifully made, and a fine specimen of Mr. Wray's work.

Following this, Mr. G. G. MITCHELL exhibited a new ferro-prussiate paper, demonstrated the simplicity of the process, and stated that the paper, the changes in whose colour were very subtle and difficult to distinguish, was issued in two qualities—one a strong form for white lines on a blue ground, the other for blue lines on white.

Dr. NICOT briefly summarised the chemical changes undergone by all forms of the cyanotype, and said:—The method of printing known as the "cyanotype," or more generally as the blue process, depends on the different reactions of ferrous and ferric salts with ferrocyanide and ferricyanide of potassium. These may be tabulated thus: A ferrous salt gives with ferrocyanide of potassium a white precipitate, becoming blue on exposure to air. With ferricyanide of potassium, a blue precipitate (Turnbull's blue). A ferric salt, on the other hand, with ferrocyanide of potassium gives a blue precipitate (Prussian blue). With ferricyanide of potassium, a brown colouration. Both ferric salts as a class, and ferricyanide of potassium, are sensitive to light, especially in the presence of organic matter, reduction taking place to ferrous salts and ferrocyanide of potassium respectively, which are able to give blues when treated with ferricyanide of potassium or a ferric salt, as the case may be. When the blue process is worked on what may be termed the development plan—that is, when the paper is coated with the ferric salt alone—and the ferrous salt produced by the action of light is converted into Turnbull's blue by immersion in a bath of ferricyanide of potassium, the latter salt is the developer, the former the sensitiser; but when the paper is coated with a mixture of ferric salt and ferricyanide, then both salts are sensitisers and both developers. For the action of light is to reduce in part both salts, and the reduced part of each reacts on the unaltered part of the other to form a mixture of Turnbull's and Prussian blue. And it may be noted, that while in the development method no amount of exposure will prevent the formation of Prussian blue, in the mixed solution method over exposure will tend to reduce the depth of colour, and if carried to excess prevent the formation of all colour. In working either method, it is necessary to use only freshly prepared solution of ferricyanide of potassium, made from clean crystals of the salt, for both the solid and solution are reduced by light alone. And if the organic salts of iron, such as oxalate, are used, the same precaution must be taken with the iron salt.

Mr. FORAN said he thought it would be well if the members would consult the original formulae for these processes, which were the invention of Sir John Herschel. Members would find them debated in Robert Hunt's *Photography*, where more than one process was given on the invention of Sir John. He had watched the process more than thirty years ago, and was then in the custom of sensitising the paper with one of the salts and developing with the other. It was also, he thought, an advantage to give the picture a wash over with a portion of the gold toning bath, which, he thought, very materially helped to give stronger results, and deepened the blue colour.

Mr. W. F. WALKER attributed the discovery of the sensitiveness of iron salts to light to the Swedish chemist Scheele, giving Captain Abney as his authority.

Messrs. WALKER, HASTFORD, and TURNBULL concurred in advocating a hard non-absorbent paper as the most suitable, in recommending the addition of an organic size, in advising the application of the sensitive solution to the surface only, and in washing the salt before dissolving it for use, to free it from acquired impurities.

Mr. TURNBULL further stated that, in cases of over exposure, reduction of density could be effected by treatment with an alkali.

Mr. WILLIAM HUME exhibited a number of transparencies by means of the oxyhydrogen lantern, commenting on technical points of interest bearing upon practical photography. Prefacing his remarks with a statement of his belief that the exhibition of "negative results and positive failures," and a discussion of their cause and cure, had a considerable educative value, Mr. Hume argued that while doubtless the bringing forward of successful results and finished pictures tended to hold up for imitation a high standard of excellence, nevertheless, many who might be anxious to attain the same perfection did not learn as much as they might otherwise do of the methods by which such admirable quality might be obtained. After contrasting some examples of the flatness arising from over exposure with the harshness caused by under-exposure, Mr. Hume suggested that a weak negative, when full of detail, might yield, under judicious treatment, a thoroughly plucky and beautiful picture, and in illustration of this view exhibited a brilliant transparency, and the feeble negative from which it was made. Passing on to suggest the action productive of flatness and harshness, slides exhibiting so-called "halation," and others in which the contrast of the natural scene was so great as almost to preclude a successful mean exposure, were thrown on the screen. One picture, a reach of the Tay at Aberfeldy, with dark foliage on the banks, suggesting the need for treatment known as auxiliary exposures for the darker portions of the subject. He also explained a method of finally obtaining contrast in the case where a very short exposure on a strongly contrasted subject necessitated the employment of a developer comparatively weak in pyro and strong in alkali, and showed that the weak resulting negative might very successfully be locally intensified by oiling the portions which should remain transparent, and then immersing the negative in an aqueous intensifying solution, thus taking advantage of the physical repulsion exercised by oil upon water. Having briefly exemplified the value of a natural background to a portrait, whether of man or beast, Mr. Hume also insisted upon the importance of taking the requirements of good composition into account in masking off injurious superfluities in the finished transparency, maintaining a pleasing proportion to be greatly preferable to a plethora of fact. While stating his preference for rapid exposures and slow development, Mr. Hume was careful to point out the danger of mistaking the clever registration of a motion for a picture. This he demonstrated by the exhibition of a slide, showing a man, a boy, and a dog in the act of leaping over a lawn-tennis net. Here, he pointed out, the very truth of the attitudes, fixed and immovable, though indicating rapid action, produced an impression which, if not positively

annoying, was in direct antagonism to artistic taste, which requires that a true picture be possessed of a feeling of repose. Leaving the photographing of near objects in comparatively violent and unstrained effort, Mr. Hume touched upon some of the causes of failure to which one is liable when aiming at the reproduction of more distant if almost equally fugitive effects, specially instancing the utter unsuitability of a short-focus lens for off-shore subjects. Mr. Hume then exhibited some beautiful slides of icicles, and also a lightning flash, and the effects of a lightning stroke upon a boy's arm, remarking that all photographers who had the leisure, the opportunity, and the skill, should endeavour to secure photographic records of any interesting natural phenomena that came in their way, for these were sure to be appreciated in the proper quarters. Finally, Mr. Hume exhibited two extremely happy examples of the successful combination of artistic effect with skilful technical handling—one being a sky of great power and gradation, the other a broad, soft, mystical rendering of a sunset view of Duddingston.

Mr. Hume was cordially thanked for his exhibition and remarks.

THE first popular meeting of the session was held in Queen-street Hall, on Thursday, January 17, Mr. W. T. Bashford, Vice-President of the Society, occupying the chair, when Mr. David McGibbon, F.S.A.Scot., delivered a lecture on *Scottish Castles*, illustrating his subject with a series of transparencies, kindly lent for the occasion, free of all charge, by Messrs. G. W. Wilson & Son, Aberdeen, and by slides made from Mr. McGibbon's own drawings.

The lecture was preceded by a short musical entertainment provided by Mr. McGlashan. The singing was very well received by the audience, especially the "Laird o' Cockpen," by Miss Bessie Simpson; the duet, "Maiden Fair," by Mrs. Wilson and Mr. Barr; and the song, "Oh, why left I my Hame?" by Mrs. Wilson, was enthusiastically encored.

Mr. Turnbull presided at the oxyhydrogen lantern, and very materially contributed to the success of the evening.

Correspondence.

✎ Correspondents should never write on both sides of the paper.

THE JENA OPTICAL GLASS.

To the Editor.

SIR,—So much has been written about the marvellous properties of the new Jena Optical Glass, not only for microscopical objectives, but also for photographic lenses, that doubtless many of your readers will be anxious to send to Germany for some of these recently puffed-up lenses. From the glowing accounts which have appeared in the various journals devoted to photography during the last three months, many of our readers must have hesitated to part with their money for English lenses, which they greatly wanted, until the mystery attached to the Jena glass lenses has been cleared up.

About a fortnight ago I requested a friend of mine, who was going to Berlin, to call on Hartnack and Herr Miethe and purchase one of these new lenses for me at any price. On his return he met me with a long face, and explained that he could not get a sample, for the simple reason that only one had been made, and that they did not intend placing any on the market, at least not for some months, if at all. With regard to the one lens which had been made, the reply was so unsatisfactory that my friend has serious doubts as to whether it has ever been made at all. Of all the forty-four kinds of glass catalogued by Schott & Co., I find the only kinds protected by patent are, with a single exception (a heavy barium silicate), those containing boron, and these are only seven in number, hence the greater number of kinds can be manufactured in this country, and, excepting two, they include all the specimens with a refractive index above 1.61 for the D line. Still, for all lenses working with a very large aperture the Schott glass undoubtedly seems to afford certain advantages, if one may judge by the covering power. Mr. Swift, Mr. Crouch, and Mr. Suter, have for some considerable time past made their photographic lenses of the new Jena glass, and I worked with one of these lenses all last summer, and it certainly fulfils all that Herr Miethe claims for him; but whatever they do in Germany, I am certain we can beat them with their own glass in England. It is a very significant fact to my mind that the chief photographers in Berlin, whose studios I visited last spring, were (and are still) working with Dallmeyer's lenses, some of them recently purchased, and preferred them to the best German makes, although the latter certainly have the advantage in price. All our leading opticians are experimenting with this glass for photographic lenses, and we may be certain whatever advantages they possess the practical common sense of the Englishman will speedily discover and adopt. One thing is certain, that so long as the German photographer finds it worth his while to send to London and pay Dallmeyer's price for his lenses, when he can get the new Jena objectives on the spot, we may keep our minds in peace and spend our money at home.

When Carl Zeiss startled the microscopists with his apo-chromatic oil immersions two years ago, Mr. Powell procured some of the Jena glass and beat him on his own ground, as was unanimously acknowledged by those present at a meeting of the Royal Microscopical Society, and if that can be done in microscopic objectives we certainly need not fear competition in photographic lenses.—I am, yours, &c.,

14, Stratford-place, Oxford-street, W. G. LINDSAY JOHNSON, M.A.

GAS EXPLOSIONS.

To the Editor.

SIR,—I thank you for sending me an account of the latest gas explosion, of which I had not previously heard in these remote parts. The letters of Mr. Chadwick and Mr. Baker, with your own leading article, leave nothing more to be said on the subject, except, perhaps, to caution lanternists against using condensed oxygen in conjunction with coal gas or hydrogen in a bag, which they might be tempted to do if a second bottle were not at hand. Supposing one hundredweight to be on the bag, that would be equivalent, perhaps, to seven inches of water, whereas the "O" gas would be issuing from the cylinder at, say, forty inches of water, and this inequality might, I think, lead to a portion of the oxygen finding its way into the "H" bag.

I have heard of two awkward accidents happening from cylinders of condensed "O" used with ether. One was several years ago, and the gas was turned on too quickly without any regulator. It rushed through the indiarubber tubes and ripped them up from end to end, but the pumice chamber prevented the flame passing back into the Broughton tank. The other accident happened last year, and in this case also there was no regulator on the cylinder. The operator turned off the taps at the end of the lecture, and he says he made the mistake of turning off the "H" tap before the "O" tap (which is what I myself regularly do). The flame backed down the tube into the Ives' saturator, and melted a big hole in one end of it; there was no pumice extinguisher.

Messrs. Cutts & Sutton sent me one of their porous saturators, and I have used it since, in order to give it a fair trial. I honestly believe that it is safe as regards a dangerous explosion, but it is not as perfect an instrument in the working as the vapour tank. The oxygen left in the barrels seems to act on a portion of the ether, and render it less volatile, so that even if you employ the lightest methylated ether, free from water, after a time you notice that the "saturation" is not so complete as it was when the saturator was new and lately filled, so that you are obliged to alter the taps two or three times during the lecture, whereas, with the vapour tank, the proportion of ether keeps up so steadily that it is not necessary to touch the taps at all during the whole of the lecture.—I am, yours, &c.,

F. HARDWICH.

Shotton Vicarage, Castle Eden, Co. Durham, February 22.

COMPRESSED GASES IN CYLINDERS.—A SIMPLE TEST APPARATUS.

To the Editor.

SIR,—As it is now admitted that there is no danger whatever attending the use of compressed gases (oxygen and hydrogen), so long as they are contained in separate cylinders and not mixed; but the question arises, "How can one tell easily and safely that they are not already mixed when delivered to the purchaser?"

The first thing that should be done, before using, is to try the gas by the sense of smelling. If hydrogen (which should be in a cylinder coloured red), it soon betrays itself when a little is let out; but if oxygen (in a black or green cylinder), it should have very little smell. If either are the least doubtful, I use the following simple test apparatus, which any one can make for themselves:—Procure about six inches of quarter-inch soft rubber tubing; next two stopcocks or gas taps, and bind one to each end of the tube; then fasten a stouter piece of rubber tubing to one of the taps for connecting to the cylinder nozzle. When connected, open the tap nearest the cylinder, and close the other. Now turn the valve of the cylinder carefully until the gas slowly expands the rubber tube between the two taps (but not sufficient to burst it), then turn all off again, and you will have a small sample of the contents of your cylinder. To test same, remove the apparatus from cylinder, and, supposing it to be pure oxygen, place a piece of brown paper, lighted, and at arm's length, opposite and close to one of the taps. When opened, the gas, if pure oxygen, will simply cause the flame to burn brilliantly; but if mixed gas, and therefore dangerous, it will explode with a sharp report, the quantity being too small to do any harm. If hydrogen only, it will burn quietly, like a common house-gas jet. For those who do not care to make the apparatus themselves, the whole can be purchased from Messrs. Archer & Sons, Lord-street, Liverpool, for the sum of 2s. 6d.

I may say, in conclusion, that I have never yet found any cylinder with wrong gas in, and think it improbable for a mistake to occur in filling.—I am, yours, &c.,

W. J. ARCHER.

February 19, 1889.

P.S.—Making the cylinders with different sized threads or connexions would not avoid their being filled wrongly, as they have all sizes at the works, and it is little or no trouble to couple on any size. It would be much better to make the oxygen cylinders with right-hand threads, and the hydrogen with left-hand. This would make it impossible to connect wrongly by mistake.

RETOUCHING.

To the Editor.

SIR,—Number 1502 of THE BRITISH JOURNAL OF PHOTOGRAPHY contains some remarks by the Archbishop of York on retouching, which I

consider sufficiently weighty to awaken the attention of the photographic profession.

Retouching as it is now going on is quite enough to spoil the reputation of the photographic art. There will be a box of negatives brought in for the retoucher, and it is expected from him to work them up in half a day or a day's time. He gets no idea how the person looks, nor even a print as proof to look at. Remains there any guaranty that the likeness will be not spoilt? how is it possible to do the work in such a way consistent with the law of art? A lot of negatives which would have been cast aside in former times are now stippled up and used as worthy representations (?) of the photographic art.

Should it not be the duty of every photographic association holding an exhibition to set apart a section for unretouched photographs?—I am, yours, &c.,

Liverpool, February 25, 1889.

PERMANENT HYDROQUINONE.

To the Editor.

SIR,—We read recently in your JOURNAL two letters from Messrs. A. & M. Zimmermann, the English agents of Messrs. Schering of Berlin, calling in question the chemical purity, and by inference depreciating the efficiency of Dr. Byk's "permanent" hydroquinone, which for some months we have been supplying to photographers in this country.

We had not intended taking any notice of these letters, but a communication received from Dr. Byk, bearing on your leading article of the 15th ultimo, has induced us to trouble you with these few remarks, which we trust you will do us the favour of inserting in reply.

In introducing the permanent hydroquinone for photographic use, Dr. Byk was actuated by the desire to provide a preparation which should be more reliable in its character and possess greater uniformity of action without losing in the slightest degree its efficiency—than those hitherto in the market; in fact, his object was to study the practical requirements of photographers rather than to advance that scientific accuracy which appears to form so great a point in Messrs. Zimmermann's creed.

That Dr. Byk succeeded is shown by the greatly increased demand we have had for the "permanent" article, by the recent general adoption of hydroquinone where previously it had been shunned, and by the fact, as proved by your own examination of some months ago, as well as by innumerable more recent testimonials, that it is at least equal in quality to any other make.

It is amusing to us to find our good friends and rivals suddenly assuming the rôle of champions of "chemical purity." It is not so very long since Messrs. Zimmermann, speaking of Dr. Byk's ordinary hydroquinone, informed a member of our firm that its extreme purity was unnecessary to the photographer, yet now, ostensibly in the interests of science, they object to the presence of an infinitesimal trace of a valuable preservative which is in no sense an adulterant, and too small in quantity to prove in any way detrimental.

They are not, however, even accurate in their complaint, since they state that "several per cents." of sulphurous acid have been found in the new preparation. We are not acquainted with our friend Dr. Byk's method of manufacture, but we have it on his authority that the preservative agent is present in the proportion of about $\frac{1}{2}$ % (one quarter per cent.), and that it does not in the slightest degree affect the developing power. These statements are quite in accordance with the various accounts, including your own, that have been received of it in this country and elsewhere, all of which go to prove that "permanent" hydroquinone is a boon to the photographer, and promises to become the standard article as well as the favourite developer for all purposes.

If Messrs. Zimmermann are so keenly interested in the scientific side of the question, and so jealous of the absolute purity of chemical products, they might, at least, be content to permit others to turn their attention to practical efficiency. If the extremely "delicate" preparation sent out in such a state of purity by Messrs. Schering be not preferred by photographers to the impure (?) article emanating from Dr. Byk's laboratory, it is proof only that practical men look more to working results than to sentimental considerations; and that though chemical purity may be a very excellent "watchword," it does not form the sole secret to commercial success. Apologising for taking up so much of your valuable space.—We remain, yours, &c.,

BRENNSTEIN AND VOGT.

27 and 28, Jewry-street, London, February 26, 1889.

THE BRIGHTON PHOTOGRAPHIC SOCIETY.

To the Editor.

SIR,—I am sorry to occupy your space with a controversy which is of very little interest to your readers, but I am compelled to answer Mr. G. Foxall's letter which appeared in your last issue. Why did he not say anything about the attempts made last June or July to form the Society? or has he joined the Society since, and the success so far due to this? Mr. Foxall knows nothing about my introduction to the promoters of the Society. I was the first to communicate with them—no one was present at my interview with Mr. Rean, and that meeting did not last five minutes. Mr. Foxall evidently has "much to learn" about the formation of a society—especially the right of members to discuss its rules. It

should be borne in mind that most of its members were elected at the meeting on the 7th—before the rules were discussed and passed—but as they were not members (so Mr. Rean argues), they were not invited to attend, and this is what I maintain is unfair—the most natural inference drawn from the form of application of membership, that all applying before the 7th would be members without election, as subsequent applicants would have to pay an entrance fee of two shillings and sixpence. Furthermore, the first regular meeting was convened for the 14th; this should show that any previous meeting was irregular.

One would think from the tenor of the letters that I was in opposition to the Society—on the contrary, I am working for it; but I am afraid that the small subscription (five shillings) will not defray expenses, unless some "good Samaritan" give the use of rooms free, and even then the postage alone will be a large item in the expenditure. I personally think it would have been better as a Club, with a minimum of officers; but the "beer and bacca" (this is the expression of the intelligent scientist referred to in my last) might mitigate against the success. I am not a "beer or bacca" consumer. This letter must be considered also a reply to Mr. Rean. In consequence of the extraordinary proceedings of the 7th, the Society has lost, by resignation, the cleverest amateur in England.—I am, yours, &c.,

A. L. HENDERSON.

P.S.—Mr. Rean should have sent invitations to the gentlemen proposed, so that if they were elected they could have taken part in passing the rules.

COLLODIO-BROMIDE.

To the Editor.

SIR,—In your number of the 18th ultimo (received here to-day), I see a letter from Mr. W. Brooks repudiating all liability for the formula for collodion emulsion for transparencies mentioned by Mr. F. C. Beach in his discourse to the New York Society. I presume Mr. Brooks imagines that the formula is my invention, and so he designates it as "most ragged in the extreme." Now, unfortunately for Mr. Brooks, the formula is one given to me by one of the leading lights in photography in England, and was, I believe, first published by Mr. J. Nesbit. I have tried the formula and sent my first results home to the North London Society (of which I have the honour to be a member), and they were pronounced "excellent," so it only shows that even Mr. Brooks's judgment is not to be relied upon in everything.—I am, yours, &c.,

FRED. D. DUNSTONVILLE.

Madras, February 6, 1889.

Exchange Column.

*. No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

12x10 studio camera (extends three feet) and lens; wanted, accessories and back-grounds.—Address, C. F. HEWITT, Weymouth.

Wanted to exchange 8x7 cloth backgrounds and interiors for others same size.—Address, E. J. HOLMES, Post Office, Cranbrook.

Will exchange Lancaster's half-plate camera, complete, for B-flat clarinet, by good maker.—Address, CAMERA, 110, Southgate-road, N.

Half-plate portrait lens, by Pillisher; wanted, posing chair or other accessories in exchange.—Address, RAWSON, Photographer, Sudbury, Suffolk.

10x8 mahogany bellows-body camera, one single slide, or eleven-inch burnisher, in exchange for good tripod for 12x10 (sliding preferred).—Address, A. E. BARNSTEN, 66, Oxford-street, Southampton.

Wanted, a half-plate bellows-body camera, double slide, tripod, and rapid rectilinear lens; exchange, silver lever chronograph, compensation balance, &c., jewelled actions, perfect order.—Address, BAIROS, Penn-road, Wolverhampton.

Answers to Correspondents.

*. Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

J. WOOD.—It is probable that Aspinall's enamel will be the best for your purpose.

F. E. J.—A good soda developer is to be found on page 629 of the last issue of our ALMANAC.

SILVER.—You will find the information you desire in the article on Daguerreotype in this issue.

CABINET.—A mount of medium stiffness is invariably to be preferred, but it is largely a matter of taste.

HYDRO.—You will find valuable information on this subject in an article by Mr. Swan, in another page of this issue.

MATHERBANK.—Our knowledge of the various iron printing processes is confined to those published in our ALMANAC.

J. F. BLACKMORE.—We believe all the portrait lenses on the list may be depended on as being good and reliable.

R. RAYNER.—The Ordnance maps are all produced by photo-zincography. They are not printed from type-blocks, as you have been told.

F. D.—The stains are caused by the prints lying in the bottom of the fixing dish, which has prevented the hyposulphite of silver from being removed.

GEO. R. SPENCER.—We understand that there is a likelihood of Mr. Henderson writing a work upon ceramic enamels on his return from a contemplated trip to Australia.

THOMAS.—There is now no difficulty in obtaining good and reliable hydroquinone. It may be had from any dealer in photographic goods. Refer to our advertising columns.

CARBOX.—1. Full directions will be obtained from a manual sold by the Autotype Company, who also supply the requisite tissue.—2. Cyanide of potassium and iodine.

R. SMITH.—1. You will find the subject treated upon, chemically, on page 177 of our volume for 1881.—2. Not much, unless the emulsion has been exposed to light.—3. Not materially.

REX.—Move the lantern and screen further apart and you will get a larger disc, or, if room will not permit of this, employ a lens of shorter focus. The size of your condenser is no detriment.

C. DAVIDS.—In working the single transfer carbon process the prints will be reversed unless the negatives themselves are reversed. For ordinary negatives the double transfer process must be employed.

S. STEVENS asks if fusible metal will answer for taking casts from gelatine reliefs, and where it can be procured.—Fusible metal will take very sharp casts from gelatine reliefs. It may be had from any operative chemist.

P. McNALLY.—Common glue is not a reliable mountant for photographs. It is usually acid, besides containing other impurities which may act injuriously on the picture. Use a good sample of English gelatine, such as Nelson's.

JAS. TAYLOR.—Cut an aperture of the desired form in a piece of cardboard, and interpose it between the lens and the sensitised surface; by moving it slightly to and fro during the exposure a softer vignette will be produced.

SIXA.—The French *mètre* is more than a yard, being 39·4 inches. The focal length of the lens is about equivalent to fifteen and a half inches, and it will, with a moderate stop, cover a twelve by ten-inch plate, or at least it ought to do so.

HYPO.—Zinc will do very well for a washer provided it receives a good coating of Brunswick black. Yours have evidently not been protected in that way. Solder up the holes and coat it. Lead or any other metal will answer if thus protected.

AXAX.—The lenses mentioned, while all of them are good, fetch so small prices in the London market and auction rooms and at the various second-hand dealers' stores, that we would be chary in offering any opinion as to their market value. About one-third of their catalogue price would be a liberal estimate of their value.

A. T.—Very few lantern slides are now made by the albumen process. It has generally been superseded, for commercial work, by wet collodion, by collodio-bromide, and specially prepared dry plates as advertised. The albumen process, though giving excellent results, is considered by most people too troublesome for general work.

W. Y. writes: "Four ounces of hyposulphite of soda to the pint is usually recommended for fixing prints. Would a bath of six or eight ounces to the pint make the prints more permanent?"—No, not if sufficient time be allowed for the weaker solution to do its work. The stronger solution would be liable to reduce the prints or affect the tones.

S. G. F.—The print is fairly good, although the development has been carried rather too far. Fix for five minutes; no toning bath is required. Instead of attempting to burnish a developed print, squeeze it upon a sheet of glass which has been well cleaned and rubbed over with powdered French chalk, which must afterwards be dusted off. The print is allowed to dry for at least twelve hours, then stripped off.

ARMENIAN says: "I made up some matt varnish according to a formula I saw in one of your ALMANACS, but I find that, instead of its giving a ground-glass surface, it dries perfectly transparent like ordinary negative varnish. Should it be applied to the plate while it is cold, or should it be warmed? I warmed the plate in the usual way."—This accounts for the transparency. The varnish must be applied to a cold plate. It is the "chilling" of the varnish that causes the matt appearance.

S. L.—Our opinion is that the spots completely spoil the photograph. If you wish us to indicate the cause of them, it is impossible to do so without some information as to how and under what conditions the print was produced, and when the spots first made their appearance. Careless manipulation will produce similar spots, so may an impure mountant or mount. As we have said before, it is impossible to indicate the cause of the spots from merely seeing two or three square inches torn out of a picture.

ALIQUIS writes:—"Will you allow me, through the medium of your columns, to thank these correspondents who have so kindly responded to my inquiries as to photographing in Norway? I must say I was somewhat perplexed on seeing such opposite opinions as those expressed by the Rev. A. M. Macdonald and G. A. K. Nevertheless the information furnished by these gentlemen, and also the entertaining letter of Mr. Kenric B. Murray, will probably prove useful to me, and will doubtless be interesting to the bulk of your readers."

REX.—1. The ground glass is intended to leave a hazy disc on the screen, during the continuance of which the picture is changed.—2. Send 1s. 6d. with two unmounted prints to our publishers, giving particulars of subject.

LANTERN writes: "Can you tell me if the copyright in Bartolozzi's engravings is still in force—I mean those printed in red ink? I have recently seen some reproductions from them, and I should like to make some slides from these."—The copyright in the engravings has long since expired, so that you can copy them as much as you like. There may, however, be a copyright in the reproductions from them, and you might get yourself into trouble if you copied those. By working from the originals you will get better results, and will, at the same time, run no risk.

T. S. says: "I will thank you for an answer to the following:—1. I have started painting photographs in oil colours, but am beaten for a good varnish for the same to use directly the colours have got dry. Can you give me a formula for a suitable varnish?—2. Also can you tell me the price and publisher of a book on carving and gilding picture frames? There is a book published, but I have forgotten who by."—1. Mastic varnish, which may be obtained of any artists' colourman. It is difficult to make in small quantities.—2. The *Carver and Gilder's Guide*, published by Kent & Co., Paternoster-row. The price, we think, is about three shillings and sixpence.

OPTIMUS puts the following queries: "1. Does pyro keep better in the dark when dissolved in water, and is it best stoppered or open? Same question regarding iron sulph. and potass oxalate.—2. How would you mix spotting colour so as not to come off in burnishing?—3. What kind of gas burner is suitable for enlarging with, and where obtainable? (I have heard of two circular flames, one inside the other. Is such a burner good?)—4. Which is best for studio curtains, white or dark material? and, 5. What is the best colour to paint studio?—6. Are combination lenses preferable to separate lenses? I mean those which interchange to make several foci."—Replies: 1. The solutions should be kept in closely stoppered bottles. The light will not materially affect them.—2. Mix the colour with albumen.—3. An argand burner will be suitable.—4. All depends upon the aspect of the studio. If, for example, it faces the south, white blinds will not stop out the sun, therefore dark must be used. For a north light, white, or very light, will answer.—5. Any unobtrusive colour, not too dark, such as a French grey.—6. Not preferable, but, as a matter of convenience, they are useful.

REV. ELI EADES says: "Would you be so kind as to inform me whether you know of any apparatus or camera for taking direct enlargements of insects of the size of a bee—and by reflected, not transmitted, light—of still-life, or otherwise; or could I take them the same size from life in any of the detective cameras? I have not found an apparatus at present to do such work. I want to work for transparencies three and a quarter inches square, when I can see my way to do so. I see some excellent articles in the ALMANAC which seem to show the practicability for an amateur to print from book engravings by magnesium or flash light, and should like to get an effective camera for such work. It has occurred to me that a camera could be attached to a lantern aplanescopescope and the object brought to the opening or stage as a *carte-de-visite* now is, and that thus one might get direct enlargement by reflected light; but I do not know of any such. It would be a queer-shaped affair, but, if effectual, would be very useful. Could you favour me with a hint as to its practicability?"—In reply: Let us assume that the object to be enlarged is a bee which has been attached to a suitable background, say a piece of cardboard, with a camera of any dimensions, but, preferably a small one, and a lens of short focus, say from three to five inches. Focus the image on the ground glass; observe that to obtain the image of the same dimensions as the original the lens must be twice its focus from the object, the same distance intervening between the lens and the ground glass of the camera. This is the rule for copying an object its own size, but you wish also to produce an enlargement of the object; in this case the camera must be pushed forward so as to bring the lens a little closer to the object, and the ground glass drawn much further out. The precise degree of enlargement depends entirely upon the extension of the camera and the proximity of the lens to the object. For example, if the bee is half an inch, the focus of the lens three inches, and the enlargement to be four diameters, i.e., two inches, then must the lens, measuring from its centre, be three and three-quarter inches distant from the object and fifteen inches from the ground glass; but any other dimensions and distance can be determined by experiment.

ERRATUM.—The article in last week's JOURNAL attributed to W. Lane, jun., should have been W. Lang, jun.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, March 6, 1889, will be on *Hydroquinone*. Mr. J. B. B. Wellington will read a short paper on this subject.

RECEIVED.—A *New Principle in Heliochromy*, by Frederic E. Ives; *South Africa*, by Ed. P. Mathers; *Dictionary of Photography*, by E. J. Wall; Fleming's Explosive Gas Tester (J. H. Steward); Grinstead's Improved Shutter. These in our next.

No. 1505. VOL. XXXVI.—MARCH 8, 1889.

THREE SYSTEMS OF MOUNTING PRINTS.

THERE are three systems by which prints may be mounted, all of them possessing advantages peculiar to themselves.

That in general use is the time-honoured one of applying paste by means of a brush to the back of a wet pile of prints placed one on top of the other as a matter of convenience, and then deftly transferring each print thus treated from the top of the pile to the mount, upon which it is laid down in position and pressed into contact by a pad or rubber. No special precaution or care is requisite in carrying this system into effect beyond seeing that the paste is free from hard particles and is freshly prepared. Glue or gelatine, which is employed by some as a mountant in preference to starch or paste, requires more dexterity in its employment.

A second system, introduced about sixteen years ago, consists in sizing the mounts with any suitable adhesive of the gum or dextrine class, these being kept in a state of preparation always ready for use. The print requires no pasting or other treatment, but may be taken while simply in a wet or moist state and laid down in its place on the dry mount, followed by the rubbing requisite for ensuring contact. This system is very convenient in many cases, especially for one who desires the occasional mounting of a few prints without having to experience the trouble of preparing paste, and going through the whole operations consequent upon the act. We are glad to know that mounts ready gummed are now commercially procurable. Those who desire to prepare mounts for themselves must be careful in selecting a gum of a suitable nature. It may be applied by a sponge or large flat brush, although preferably so by a little machine for the purpose introduced by a Halifax firm, and exhibited at some of our societies a few years ago.

The third system is one which is adopted much more extensively in America than in this country, and is highly suitable when large quantities of prints are to be mounted. As witnessed in operation in the States six years ago, when many thousands of prints were undergoing this process, we specially noticed its neatness, the rapidity of its action, and the impossibility of producing cockling. The backs of the prints are coated with ordinary starch paste and allowed to dry. The prints are then trimmed and laid *in situ* on the paper (or card) mounts to which they are thenceforth to be permanently attached, which mounts, however, have first been rendered slightly damp. A number of prints thus prepared are then run through the rolling press, and the operation is complete.

PHOTOGRAPHIC APPRENTICES.

A somewhat important question comes to us from a professional photographer in one of the provincial towns, which may be

worthy the attention of those who are in the habit of taking apprentices, as to the working of the indentures. Our correspondent says:—

"Two and a half years back I took a young fellow, aged seventeen, with a premium, as an apprentice for a term of four years, paying him a weekly salary, increasing each year. He has worked with me in the studio and out of doors, assists in the retouching and printing, and is now a very useful hand. He has, I find, been offered higher wages than I am paying him by another artist in the place. . . . The friends of the youth have just given me notice, that unless I agree to cancel the indentures and return the premium, they will take legal proceedings, because, they say, I am not teaching him every branch of the art, according to the agreement. The friends say he ought to be taught to prepare his own plates, sensitise paper, work the collodion process, platinotype, and to do enlarging. I, like every other photographer, buy my plates; I use ready sensitised paper, and always have; and have never tried the wet process in my life, as I commenced photography since that was discarded; neither do I work platinotype, or do my own enlarging."

The foregoing involves questions as to what an apprentice can legitimately be expected to be taught in a photographic business. Clearly, in the one in question, there is not much to command a high premium and low wages for several years, seeing that only dry plates and silver printing are employed, and for the latter the paper is purchased ready sensitised. In the wet collodion days an apprentice had much more to learn than he has at present; but he was not usually taught obsolete processes, such as the daguerreotype or calotype for example. Can the wet collodion process, however, yet be considered obsolete, seeing that it is still being extensively employed in some establishments? Are the preparation of dry plates and the albumenising of paper things which an ordinary apprentice must be taught? "Every branch of the art" is a very comprehensive term, as it embraces every form of photography, as well as all the different processes of printing and enlarging. If the term were applied literally, it is a question whether some of the photo-mechanical processes would not have to be included, or at least the truly photographic portion of them.

In drawing up indentures of apprenticeship, the deed should be clearly worded as to what branches of photography are to be taught, and these even should be strictly defined, particularly as photography has now so many ramifications. Such vague terms as "every branch of the art," "thoroughly teach the trade," &c., should be strictly avoided.

PRACTICAL CONSIDERATIONS IN STUDIO BUILDING.

In its broader aspects the subject of studio building has been treated with a certain amount of fulness by various authorities; but when a photographer once completes such a structure, even when erected after his own instructions, he often finds

that improvements might have been made that are not included in his plans, and, almost as often, that improvements which are included were accompanied by certain drawbacks in practice that were not foreseen. Some of these less frequently noted points will be dealt with in these articles, not so much with the intention of presenting them in the light of novelties, as with the purpose of supplying a hiatus in the literature of the subject by dealing with them in a regular consecutive manner.

ORIENTATION. The direction with regard to the points of the compass is the consideration that would naturally first seem to demand attention, as all building plans will be founded upon it. Too frequently the direction in which a studio can be built is not a matter of choice at all, hard facts in the shape of bricks and mortar intervene, and it must be built in a certain way or not at all. But, again, when there is some little room for the exercise of judgment, there is danger that owing to the worship of a certain fetish a plan may be chosen in which the best capabilities of the site are not made use of. Of the special topic we are now dealing with there is, perhaps, no branch upon which more unreasoning dogmatic assertion has been made than that of the orientation, and yet, when we come to examine the advice and the practice of those whom all would deem authorities, *ex cathedra*, we find them strangely at variance. Each one has written from the practical experience of one or two studios in which his first ideas have been carried out, and the facility which practice has given him he rather puts down to the advantages of the mode of construction adopted. We need scarcely say that the fetish we alluded to is a "North Light." But at the outset we ask, What does a north light mean? When the dominant light comes from the north, some will reply; but how is this to be understood when the main skylight may slope either to the sitter's feet or to one side? We believe it is most frequently understood to mean a light so arranged that the sitter faces the north. But at once we must say that, under most conditions, this is a decidedly disadvantageous way of planning a studio, for reasons that we will presently make plain. These reasons will also show that, although the direction of the studio is the point that first appears to claim notice, many other considerations come in, and must be dealt with before it can be decided. Indeed, it will be necessary for several subjects to be discussed before we could say that this or that direction was the best.

We must at once draw attention to the fact, too frequently ignored, that no studio in which the dominant light cannot be directed to either side of the face at pleasure is able to allow full justice to be done to all sitters. This is a point that admits of no dispute. Some faces, taken not full, are best lighted by the major side being in light, others by its being in shadow. Even a full face may be far better represented when lighted from one side than it would be from the other. Hence, to be condemned always to take, say, the left side of a face if "Rembrandt" effects are not wanted, seriously cripples the power of the artist who wishes to please his friends or his clients. Much might be written upon this subject alone, but now we must, if we wish to confine our topic within reasonable bounds, content ourselves by reminding our readers that, as almost all faces are unsymmetrical, so in a photograph, which neither moves nor blinks, no matter how it is scrutinised, these departures from symmetry will be more noticed than in the original, which both moves and blinks, and never affords the opportunity for close examination which the immobility of the portrait renders easy. This asymmetry may be greatly dis-

guised by having a full controlling power over the direction in which the light falls upon the countenance.

There are two ways in which this power may be gained. First, by glazing the studio in such a manner that, without moving the sitter, the light by means of blinds or screens may be caused to fall upon either the left or the right side as may be desired. Second, by having such an arrangement of studio that a similar variety of illumination of the face is produced by causing the sitter to move to a different part of the room. Both plans have their advantages. It is clearly more agreeable to a sitter not to have to move about the room from spot to spot to get a suitable effect of light; the average sitter finds the whole affair sufficiently harassing and embarrassing without this additional burden. To plant himself by a chair or other support, and then to have the light arranged by the photographer, without his intervention, is obviously one means of retaining some little of his self-possession and *savoir faire* (too frequently conspicuous by their absence in portrait photography). On the other hand are to be considered the increased difficulty of keeping out the sun when both sides of the studio are glazed, with the consequent difficulty of keeping down the temperature, and also the fact that if the direct rays be kept out and the light modified by some sort of screen, it is very difficult, without one of sufficient thickness to materially "slow" the light to be used, to avoid the light falling in such a way as to approximate a modified sunlight and be so powerful as to destroy the more delicate tones and shades. In our next article on the subject we will further show the practical bearing of these points.

MR. FREDERICK HUDSON, well-known in the photographic world some ten or fifteen years ago as a most successful photographic landscape artist, has just died in Ventnor, Isle of Wight, at the age of sixty-seven. Settling in Ventnor some thirty years ago, on his return from America, he devoted himself principally to the study of landscape work, for which he found great scope in the beautiful scenery around him, and in which branch he soon made himself a name, as he produced some of the finest negatives of the picturesque spots in the island. These were mostly of a large size (20×16), taken direct by the wet collodion process, and gained for their author medals from the exhibitions in Southampton, Cornwall (2), London, and the International Exhibition at Philadelphia, U.S.A., 1876, besides the patronage of the Empress of Austria while staying in the island. Mr. Hudson, through failing health, retired from business some few years ago.

DURING a discussion at a recent meeting of one of the provincial societies a speaker mentioned that out of the six lenses, portrait and landscape, he possessed, only one of them had the visual and actinic focus coincident. If the lenses are of modern manufacture, and by makers of repute, the statement will take many by surprise. If, on the other hand, they are of very ancient date, the matter is by no means astonishing, as, at one time, lenses with non-coincident foci were the rule. It has been remarked by more than one that if the camera used by this gentleman were carefully examined, it might possibly prove that five of the instruments *did* work to focus, and that one only did not. We have little hesitation in saying that there are far more modern cameras in use in which the dark slides are not in register with the focussing screen than there are modern lenses, by good makers, in which the optical and chemical focus is not coincident.

PHOTOGRAPHERS, as a rule, appear to pay very little heed to the accuracy of their dark slides, and this often leads to the condemnation of the lenses. How many ever think of testing a new camera before taking it into use, or verifying it after it has been a year or two in

use? Lenses are now, it is true, usually employed with such reduced apertures that a slight variation between the plane of the ground glass and that of the sensitive plate often passes unnoticed in practice. But if by chance a lens with a large angular aperture be substituted, it is frequently condemned without its being in any way at fault. Whatever may be the angular aperture of a lens, it is manifest that it must always be worked at a disadvantage unless the dark slides are in perfect register with the focussing screen, however trifling may be the error.

It is the simplest thing imaginable to test the register of dark slides, and takes far less time to do than to describe how it is done. All one has to do is to cut a narrow strip of cardboard, three or four inches long, to a wedge shape. Then to place a straightedge—a side of one of the slides will answer—across the focussing screen and pass the wedge between the ground glass and the straightedge, making a mark with a pencil where the latter intersects the card. Next place a plate in the slide to be tested, draw the shutter, and repeat the operation. If the points of intersection coincide, the slide is in accurate register. If not, the amount of alteration will at once be seen.

It is somewhat of a shame that no public records exist relative to the early history, the rise and progress of photography. True, there are numerous articles and portraits in the possession of private individuals who feel an interest in what we may designate the archaeology of photography, but there is nothing of this nature to which the public have access. Mr. Lindsay Johnson, in a note to us, signifies his intention of making an endeavour to induce the Photographic Society of Great Britain, as the oldest corporation extant in this country, to make an effort and take the necessary steps to supply this much-felt want, and in this we sincerely hope he will be successful. Mr. Lang, of Glasgow, could afford valuable aid in the making of such a collection.

At the penultimate meeting of the West London Photographic Society the question was put as to whether the "continuing action of light" in carbon printing is utilised commercially. A short time back we were informed that, in one establishment where the cheap carbon pictures on opal glass are produced, during the past few months this property has been taken advantage of to the extent of seventy-five per cent., or more, in the exposure. The prints are exposed for one-fourth, or one-fifth, only of the time that would be necessary were they developed at once. They are then kept in the dark until they become deep enough. By this means four or five times the number of prints from each negative are obtained in a given time, and of course only a quarter of the number of printing frames are required under this system of working.

There is no question that a large number of photographs, which are used commercially, do fade, and that rapidly too. A short time back we had the following query put to us by a lay friend, who had been supplied with some portraits of his family which had become badly spotted within a year or so after delivery: "Can I not," he said, "proceed against the artist for the return of the money, seeing that the work was imperfectly executed?" Our advice was to return the prints and, no doubt, others would be supplied free of charge. This was done, and the result satisfactory. No respectable photographer, we imagine, would refuse to replace pictures which have deteriorated in an unduly short period, if only for the sake of his reputation. Now that there are several processes by which really permanent prints can be produced, it would, perhaps, prove a knotty point as to liability in a case of fading if the question were contested in a court of law.

ECHOES.

Our leading article on *Explosive Silver and Iodine Compounds* forms a reasonable warning to dabblers in photographic chemistry whose zeal is greater than their chemical knowledge, though in these days of commercial plates and cut-and-dried formulae the number of such experimentalists is far fewer than in years gone by.

That accidents may easily happen from the unwitting formation of such substances as those named, even to such as have a fair knowledge of all-round chemistry, without any special acquaintance with particular departments, is amply proved by the past records of photography, and many mysterious explosions and cases of "spontaneous combustion" are, no doubt, traceable to this cause.

I can give an instance in my own personal experience, dating back a good many years to my "salad days" in photography, in the shape of an unexpected incident which remained a mystery to me for a length of time, and which, though unattended fortunately by any more serious consequences than a little personal discomfort of a temporary nature, might well have proved far more disastrous.

It was, I need scarcely say, in the "good old wet plate days." I was making a batch of collodion and found I was short of iodide of ammonium, and the photographer of that period was not unacquainted with the necessity for making many of the materials he employed, sometimes because it was the only way, or frequently the readiest of obtaining them. In my case I should have had to travel or send some miles to the nearest chemist who was likely to keep the salt I wanted, so my best plan was to compound it from materials I had at hand.

My method and ingredients were to me apparently common sense ones, and the operation presented no special feature of difficulty. A quantity of iodine was thrown into some liquor ammonia in a glass measure, and its solution and combination hastened by pounding with a glass rod. Of course a due amount of care would have been exercised in the final adjustment of the proportions of the two elements, and in the process of crystallisation if only time had been allowed me, which, however, fortunately—I say it advisedly—was not the case, for, thanks to my vigorous use of the glass rod, but a short period elapsed before there was a dull report and a general "ruction" of some sort, the contents of my measure glass being scattered all over the place. Thanks to the power of the ammonia fumes, my face was not in too close proximity, so I escaped with only the suffering that resulted from the pungent vapour of iodine and ammonia that saturated the atmosphere and temporarily diverted my optical arrangements from their normal duties.

Collodion making was necessarily relinquished for the time, and when resumed, it was with a sample of iodide obtained from other sources, and the precise cause of the upset remained a mystery for some time, until I discovered that I had been proceeding upon the orthodox lines for the manufacture of one of the most dangerous explosives known to chemists. Had I been in a less hurry, and allowed the mixture to stand a few minutes before applying the glass rod, there is no knowing what the result would have been; but the incident shows that even out of two such comparatively harmless and well-known substances as iodine and ammonia a vast amount of risk may come.

I read with a good deal of interest the description of Mr. J. W. Newall's standard sensitometer, because now, more than ever, the necessity exists for some instrument which can fairly be designated by such a title. It would be absurd to claim that anything like a reliable "standard" exists. The readings of the Warnerke instrument have a certain approximate value to those who thoroughly understand it, and who conform to certain necessary conditions, but so slight a variation in those conditions as a difference in the composition of the sensitive film renders it altogether useless for purposes of practical comparison.

That refers simply to variations in the character or proportions of the various haloids employed, as the phosphorescent tablet is notoriously partial in its behaviour to bromide, iodide, and chloride of silver. But if we now add orthochromatic plates to those to be tested, it is not too much to say that the phosphorescent surface is worse than useless. Yet after very careful trials this was selected by a committee appointed for the purpose as being the most practically convenient form of illumination.

What is wanted is no doubt what Mr. Newall has aimed at, namely, an instrument capable of giving a reading in definite terms of such a duration of exposure to a standard light, preferably daylight if that can be standardised. But there lies the difficulty. I know very little, practically, about the "pentane" standard, which may be reliable enough for merely photo-metrical purposes, but for testing photographic

surfaces I imagine its chemical intensity, as compared with daylight is as liable to vary to iodide, bromide, or chloride of silver as the luminous tablet or any other form of artificial light.

The nearest approach we can make to the character, if not the intensity, of sunlight—at least in convenient form—is the magnesium light, and I think from recollection that the sensitometer committee of 1880 spoke well of this as a practical standard. No greater difficulty exists in the case of magnesium in getting a fixed amount of duty out of a given quantity than out of a given quantity of coal, and it certainly has the advantage over other artificial lights of exerting an action on the different haloids more closely resembling that of sunlight.

But the mechanical arrangements of Mr. Newall's instrument, though ingenious, are to my mind unnecessarily complex, and, moreover, require a delicacy of adjustment in order to secure accuracy in time exposures that places it practically out of court for everyday use.

Nothing could well be simpler nor more accurate in its graduations of time to the most minute fractions of a second than the revolving disc pierced with apertures bearing definite relations to the whole circumference of the circle. With such a revolving screen, pierced with holes increasing in size gradually by increments of 3.6 degrees of arc, it is possible without any elaborate mechanical contrivances to accurately divide a second into hundredths; for no matter what the speed of revolution, each 3.6 degrees of opening will give an exposure of one one-hundredth of the total time given. Such a contrivance was described some years ago before one of the London societies—the Photographic Club, I think—by Mr. W. Bedford, and would be difficult to improve, except in detail.

At the last meeting of the Photographic Society, or rather in the report of that meeting, I notice that pyrogallic acid is described as "the former salt." Either the speaker or the reporter is rather out in his phraseology, I think.

The question of treating hydroquinone colloquially as quinol is one that may very well be considered seriously, for the proposal made in more than one quarter to condense it to "hydro" is supremely absurd, and yet not more so except in its newness than either "pyro" or "hypo," all three prefixes being equally meaningless when employed alone.

Quinol, however, answers every purpose, being short and concise as well as being the real name of the substance; but there is, of course, the usual "conservatism" of photographers to be overcome even in the case of so comparatively new an introduction as hydroquinone.

The proposed Parent Society's museum would be a good idea if properly carried out, for an immense amount of interest centres in all objects of an "antiquarian" nature, if such a term can be applied to things photographic. But I should be strongly inclined to join with Mr. Arnold Spiller in wishing to keep clear of South Kensington. The "historical collection" got together for the Inventions Exhibition was, I believe, to be—or it was so proposed—relegated to that great national headquarters of "fossildom;" if it got there it certainly appears to be lost.

Chairmen of meetings have various uses, ornamental and practical, but a new one with a *souçon* of danger, or at least excitement about it, has been added to the list. Mr. Haddon, we are told, at a late meeting of the London and Provincial Association utilised the Chairman as a weight to hold down a box while he exploded some gun-cotton in it. Happy and obliging Mr. Chairman!

JUNUS.

HOOKE'S CAMERA, 1694.

To whom should we ascribe the camera in its portable form? This appears to me a question much more easily put than perhaps satisfactorily answered. From what Porta says regarding his darkened chamber and the images obtained therein, it is perfectly apparent that the Neapolitan philosopher realised the fact that the camera obscura would be of great service in assisting any one to draw or sketch. In the seventeenth book of his *Natural Magic*, which treats of strange glasses, and in that part of it which bears more directly on the various experiments he made with the camera, we find him distinctly stating, "If you cannot draw a picture of a man or anything else, draw it by this means" (English translation, 1689). It

is quite apparent that in the arrangement put forward by Porta, the thing to be drawn would require to be brought to the vicinity of the darkened room and placed in a suitable position, according to the light, before that its image could be reproduced on the whitened tablet destined to receive it.

Who, then, conceived the idea of taking a portable camera to the place where it might be wanted? It would almost appear as if we were indebted to an Englishman for the suggestion, but, be this as it may, it is sufficiently interesting to refer to the instrument which Dr. Robert Hooke brought under the notice of the Royal Society on December 19, 1694. The accompanying picture is a reproduction of the plate which figures in the work, *Philosophical Experiments and Observations of the late eminent Dr. Hooke, S.R.S., and Geom. Prof. Gresh.*

These memoirs of Hooke were published in London, in 1726, by W. Derham, F.R.S. As the title implies, its contents are varied; we may simply refer to a few of them:—"On the invention of the Barometer in 1659; Description of his Weather-wiser; on Hailstones that fell in London, May 18, 1680, with plates; on Instruments for Sounding great Depths of the Sea; on Telescopes and Microscopes; on Amber," &c., &c.

The title of the article in which we are more especially interested is as follows:—"An Instrument of Use to take the Draught or Picture of anything," communicated by Dr. Hooke to the Royal Society, December 19, 1694. After referring to the very imperfect way in which books of travel are illustrated, in a style which to say the least is verbose and which would simply weary the ordinary reader to quote *in extenso*, he goes on to say:—

"It is therefore, the Interest of all such, as deme to be rightly and truly informed for the future, to promote the Use and Practice of some such contrivance as I shall now describe, whereby any Person that can but use his Pen and trace the Profile of what he sees ready drawn for him, shall be able to give us the true Draught of whatever he sees before him, that continues so long time in the same Posture as while he can nimbly run over, with his Pen, the Boundaries, or Out-lines of the Thing to be represented, which being once truly taken, 'twill not at all be difficult to add the proper Shadows and Light pertinent thereunto. By the same Instrument also the Mariner may very easily and truly draw the Prospect of any Shore, and from Time to Time denote the Rising thereof, as he does nearer and nearer approach it, and the Depression or Sinking of it, as he does recede.

"The Instrument I mean for this purpose is nothing else but a small Picture-Box much like that which I long since shewed the Society for Drawing the Picture of a Man, or the like; of the Bigness of the original or of any proportionable Bigness that should be desired, as well bigger as smaller than the Life, which I believe was the first of that kind which was ever made or described by any. And, possibly, this may be the first of this kind that has been applied to this Use; tho' upon the first Institution of the Royal Foundation of Christ-Church I propounded it to the Governors there for the use of the Children: But Sir John More undertaking to write an Institution, and having omitted it, it has not there been brought into use."

Hooke must have taken it for granted that his picture of the instrument would be sufficiently explanatory, for in the text no description of any kind is to be found regarding the instrument. The size of the aperture, depicted in the cut, would of necessity indicate that there was a lens of some sort placed in the opening. It would be interesting if we could trace something regarding the "picture-box long since shewed the Society," but so far as I have been able I have not found anything regarding it in the printed records of the Royal Society.

It is unfortunate that a fuller description of the instrument has not been given us, but it will be apparent to any one that, in the illustration above shown, an early prototype of our modern camera is clearly to be seen.

Some details regarding Dr. Hooke may not be without interest. He was born at Freshwater, in the Isle of Wight, July 18, 1635. He showed at an early age a decided turn for mechanics. The Hon. Robert Boyle made use of his services in the construction of his celebrated air pump. This was about the year 1655. Later on he applied the balance spring for the regulating of the movement of watches. In 1662 he was appointed curator of experiments to the Royal Society. In 1665 Hooke was appointed Professor of Geometrical in Gresham College. The great fire of London took place in the following year, and Hooke had, it seems, an excellent plan for the rebuilding of the city. Although highly approved, it was the celebrated architect Wren's plan that was adopted, but Hooke got a po-

as surveyor of the works. He was secretary to the Royal Society for five years, having been elected to the post in 1677, and in 1681-82 the papers read before that body were published by him under the title of *Philosophical Collections*. In 1686 the Royal Society made him a grant, so that he might complete his philosophical inventions. This he never seems to have accomplished. Hooke died on March 3, 1703, and was buried in St. Helen's Church, Bishopsgate-street, London. Our philosopher's mind was of a higher order than his body, for it is recorded of him that he was of crooked figure and had shrunken limbs. His scientific work was in character too varied for him to thoroughly complete what, in many cases, he was the originator of. His principal writings are *Micrographia*, 1664; *Lectiões Culverianæ*, 1674-79; and *Posthumous Works*, published by Waller in 1705. The work from which we have taken our illustration would, according to the preface, seem to have been principally compiled from the papers which Mr. Waller had not made use of in the *Posthumous Works*.
W. LANG, JUN.

CHEMICAL VIGNETTER.

PROCEED thus:—Make a square cone of tin, cardboard, or wood, all blackened, similar to diagram, to fit into the inside of your camera, back part to catch behind focussing glass inside, and front part made to project about half length between lens and sensitive plate.

Now make a *carte-de-visite* vignette the usual size, and made of cardboard, and inside of front groove insert it so that it will move up and down and slightly sideways, so as to admit of the reflection being well centred on your plate.

Focus a sitter for cabinet size, usual head, and mark distance by scratch on camera bed. This is done so as to know afterwards the correct size for more of the same pattern.

Now place a very slow sensitive plate in your holder, cabinet size, and having placed a white sheet of paper a few feet from the lens' mouth, expose for a few seconds, and moving it slightly so as to show a pure white on plate. Develop with usual developer, but double pyro, so as to secure great density.

You will now, if you have proceeded properly, have a film of bare glass with a beautiful soft vignette pear-shaped in the centre of your plate. Success lies in as little exposure as possible with prolonged development, so as to get as grading an edge as possible.

Use this plate when dry as a printing mask, with which to get the reverse as transparencies.

Place your plate in a printing frame, put a thick clean glass between it and your sensitive plate, so as to secure additional softness. Now expose to a flame of gas full up, say six seconds, about four feet off. Develop with double pyro to great density, and fix as usual. You will now have a plate with clear pear-shaped vignette in the centre and dense margin; you can repeat this plan and obtain any amount of vignettes all the same size from your first plate. By either making your inside tube telescopic, or making different sized front cardboard vignette holes, you can obtain all the sizes requisite. The last is the best plan, as they are always softer when exactly between the lens and plate. Any old plates can be used for this purpose on condition of their being free from pinholes.

Should you obtain a soft margined negative as mask, but still not dense enough, either paint within an ace of the outline or paste paper on same conditions, as the object is to obtain very soft gradual outline with dense centre. Any little holes can be filled up easily. Paste your vignettes on cardboard, and use just as the old glass stained vignettes were used. Any quantity of these vignettes can be made in your spare time.

ROBERT MORRISON.

PHOTO-MECHANICAL JOTTINGS. IV.

For etching zinc blocks the following apparatus is necessary, and should be procured before commencing work, as one of the prolific causes of failure in this work is trying to do it without suitable tools:—A whirler, a printing frame, box pattern, with extra thick plate glass front, and the hinged bars fitted with screws instead of springs, a spirit stove, a type-printers' roller, an inking slab, a leather litho roller, a glazed roller, a flannel roller, a wooden tray, lined with pitch, on rockers, for etching, and a hot plate heated with gas. Zinc plates seventeen or eighteen gauge, photo-transfer, soft, and hard etching acids are also necessary.

For printing on zinc there are two processes, viz., bichromated albumen for ordinary line work, and bitumen for fine line work, and

for tint or half-tone work; for printing in albumen, the white of one egg, beaten and mixed with eight ounces of water and one ounce of a saturated solution of bichromate of potash, well-filtered, makes the best mixture. The zinc plate polished, first with fine emery cloth and turps, followed by pumice powder, is grained in a bath of nitric acid, one part; alum, one part; water, one hundred parts; then, after washing, is placed in the whirler, coated, whirled, coated again, again whirled, then removed and dried at once over the spirit stove.

Expose in the sun from four to eight minutes, in the shade from twenty to sixty minutes, then ink up with the type-printers' roller, the ink being thinned with turps. The film of ink requisite for a zinc plate is very thin; indeed, it must not be thick enough to prevent the zinc being seen underneath. The development is effected by putting the plate into a dish of cold water, and rubbing gently with a pad of cotton wool, which clears away the ink from the whites, leaving the image on the plate, and if the exposure has been sufficient it will require a considerable amount of friction to remove the image. This method is not the best for very fine line, or for tint, or half-tone work, on account of the liability of the ink to choke up the finest lines. Therefore, for such subjects the bitumen process must be used instead. Now bitumen has been used for even a longer time than albumen as a sensitising agent for metal plate printing, but when used in its crude state is so very insensitive that it is practically useless. But when the crude bitumen is purified by being washed in ether, it is only about one-third slower than albumen.

To purify the bitumen it is powdered, put into a wide-mouthed bottle, and sufficient ether, S.G. 735, as will cover it is poured in, stirred well, and allowed to stand a few hours, then well stirred, and the blackened ether thrown away. Another lot of ether is then added, the mixture stirred, then allowed to stand, then again stirred, and the liquid thrown away, the set of operations being repeated, until the ether, after standing for a few hours, is nearly colourless, when the residue of bitumen is poured into a clean and dry tin dish, and put away in a warm corner of a dark room to dry. When the purified bitumen is dry it is jet black, very friable, and thoroughly soluble in benzole. The best proportion of bitumen required for each ounce of benzole cannot be given, as each sample must be used in the proportions that suit it; therefore each sample of purified bitumen must be tried before deciding upon the proper quantity, fifteen to twenty-five grains of prepared bitumen to each ounce of pure benzole being a good guide. Whenever there is any difficulty in procuring pure benzole, benzine collas, sold by chemists, will be found an efficient substitute, but ordinary benzine of commerce is best avoided, as it is an uncertain compound. The bitumen dissolves readily and should be filtered before use.

The zinc plates are polished with fine emery cloth and turps, then with washed whiteness, moistened with a mixture in equal parts of turpentine and mineral naphtha, then put in the whirler, dusted, then coated and whirled for two or three minutes, when the film will be dry ready for exposure.

To coat the plates without a whirler will be a useless waste of time and material, as unless there is a thin, even film all over the plate a good print cannot be obtained. The best form of whirler, costing only about three shillings, is that illustrated in *Photo-engraving*, published by Messrs. England Brothers, Nottingham.

Bitumen prints are developed by immersion in a dish of turpentine, and occupies from fifteen minutes to an hour, according as the exposure has been short or long, the effect of over exposure being only to prolong the time of development, under exposure, of course, telling its own tale by leaving the zinc bare.

When the development is judged to be finished, wash the plate under a powerful rose, then immersion in a dish containing water one hundred parts, nitric acid one part, and a few seconds will reveal the fact whether or not the development has been carried on sufficiently far. If not, the plate is returned to the turpentine.

Prints in albumen are first of all gummed in and dried, then rolled up with the leather roller charged with soft etching ink, worked as stiff as possible. After this immerse in water—in which is sufficient nitric acid to just taste—for one minute to clear away the gum, &c.; then wash well, back and front, rubbing with a soft sponge, dry, and make any alterations or retouching that may be wanted—protect the back with white hard varnish, also the margin and any of the broad whites; then gum in again, dry, and again roll up, dust with powdered resin, after which the etching is proceeded with. The first two or three etchings are the most important, and require patience and a weak acid bath.

With a bitumen image the first etching is done before rolling up, so there is every chance of getting the fine lines sharp. The subsequent operations of gumming in and rolling up are the same as for albumen.

The flannel roller is used with thinnish ink when the etching has progressed too deep for the leather roller to properly touch the lines, the glazed roller being brought into use after the resist is cleared off the plate, which is made hot; then the glazed roller charged with the hard ink brought to working consistency with turps, and the etched plate on the hot plate is rolled up, the object being to touch the tops of the lines only, so that the burr caused by each successive etching may be removed without danger to the surface.

The production of negatives—grained negatives for tint or half-tone blocks—requires great care, but the making of the screens is even more difficult. The usual idea of these screens is that they must be very intense; but this is quite a mistake. The thinner they are the better; that is, within due bounds. The operator should have a selection of them varying in density and use them to suit the particular picture to be copied, the rule being the flatter the original the thinner the screen.

W. T. WILKINSON.

THE PROPERTIES OF DETECTIVE CAMERAS.

No. III.

We now conclude the summary of the properties of detective cameras. In answer to the question:—

22. *What improvements in the construction of the detective camera can you suggest?*

(a) "A method of construction so that operator could observe the whole field of the plate and focus at the same time that the exposure is made."

(b) "The ideal camera would be one carrying two lenses of seven and four and a half or five inches focus respectively, with an automatic arrangement to bring the plate to a fixed focus at the same time that the lens is changed. An automatic arrangement to bring a fresh plate or breadth of film into place after making the exposure, the shutter at the same time setting itself for a second exposure, would be a god-send. In other words, twelve pressures on the exposing trigger or bulb should expose twelve negatives, without the necessity of manipulating the internal arrangements, either by the clumsy process of opening the box, or by working slides, buttons, or levers on the outside. A strong spring, wound up at starting, could do this. A figure, seen through a slot, could visibly register the number of exposures made. A thoroughly self-contained automatic camera could be disguised in an endless variety of portable cases, and used without attracting attention, and so justify the name of a 'detective camera,' now so grossly misapplied in nearly all instances."

(c) "A swingback that would work automatically when camera is tilted."

(d) "A very difficult question to answer. A detective camera, to be useful, should not have any plate holders, but should be so constructed that it carry within itself at least two dozen plates, and so arranged that these plates could be easily transferred from one part to another of the camera with a slight movement of the box. Provisions for focussing lenses from four inches to eight inches. A great luxury would be a moveable or sliding focussing screen that could be brought into use in a moment."

(e) "My objection to the detective camera is, that not being able to focus sharply as with my regular view camera."

(f) "A detective camera should have a shutter of positive movement, balanced to prevent excessive shock, yet capable of moving fast enough to take a trotting horse passing the camera at right angle to the axis of the lens, without blur of image. Plate holders and slides should be dispensed with and means provided for bringing the sensitive surfaces into position rapidly. There should be provided temporary means for preventing the light striking the plate when the shutter is set or a self-shutting shutter arranged. Special devices are needed for easily releasing the shutter without jarring the camera at the instant of exposure."

(g) "1. That they be so arranged that at least six plates can be exposed without opening the box. 2. That the shutter can be timed accurately. 3. That it can have a practical double swing. 4. That the finder is actually in proportion to the size of the plate and absolutely correct in position. 5. That the bellows have freedom enough in movement to take a wide angle or rectilinear lens."

(h) "What I want for my own work. 1. A camera to carry fifty films (the new celluloid), with certain and rapid means of exposing them in succession. I prefer these films to roll-holder paper or films, and find that they work as well in the detective as glass plates. 2. Some easy and satisfactory way of focussing the image up to the very instant of releasing the shutter. The arrangement for focussing by estimating distance has been very unsatisfactory in my hands, and I invariably lose the view that I want the most and 'estimate' for most carefully. A camera thus fitted up needs no 'finder,' of course. 3. A shutter release at once firm and delicate, not to be set off by a jar, and yet working so easily that you do not move the camera in operating it."

(i) "Anything that will contain a satisfactory substitute for glass plates, in a roll or otherwise, in quantity sufficient to make twenty-five or fifty exposures without opening camera to change holder, and consequently will be more light-tight than present cameras and holders. Also a focussing finder which will change as the camera bellows change, so as to enable one to focus on an object instantly by looking in the finder."

(j) "The shutter should work in the centre of the lens or back of it; a more noiseless shutter would be advisable."

(k) "Slide to close the two finder eyes of camera when not in use. Shadowing hood to the finders to keep the sunshine off the ground glass of same when

sun is shining over your back or overhead. To have the top of the lid divided and hinged, so that you can introduce a holder quickly at any focus without opening entire camera box, and a means of withdrawing quickly the holder other than by your finger nails. Also an indicator to show whether or no the shutter is set without having to try the same. To have drawn on top of camera lines showing the angle of view included by lens, so that without use of finders you can be sure to have an object on the plate—a very necessary thing in quick snap work on the streets. Also a small roll holder to slide in place of plate holders. The present roll holders make the camera too bulky."

(l) "I don't think the perfect detective camera can ever exist, except in the imagination; it requires 'too many more improvements,' many of which conflict with one another. My 'detective' and other camera experience has been quite varied, and has taken all my leisure time since 1881, but it appears to me that I have mainly learned how much there is to be done in this direction. There is a wonderful fascination about the work, however."

(m) "One that will take lens from 5 to 8 inches; carry at least two dozen glass plates; set shutter and release from outside of box; expose plates without opening box or drawing slides; no external brasswork; and lock so that it will be impossible to meddle with it without key; colour, dead black."

(n) "Make it less complicated, so that it can be used instantly. When I need my detective most my experience has been that there is not time to work a complicated camera. It usually happens that by the time I am ready to shoot, the effect I particularly wanted cannot be obtained, the game has got out of range. One cannot usually sit around all day waiting for good things. They come suddenly and unexpectedly, and must be caught on the fly to be worth getting. This cannot be done if the camera will not admit of being worked quickly and easily. By the time a lens was changed, a swingback adjusted, the shutter regulated to a minute fraction of the twentieth part of a second, the slide drawn, &c., even a rheumatic mud turtle would have crawled out of sight and been lost for ever. My experience points only in one direction, viz., to the need of extreme simplicity in construction of the camera, a fixed focus, a good shutter that will let in lots of light when open, and none at all when closed, some means of pulling the slide without having to open the box, if possible a flexible film that does not need stripping, and when these are provided it will be easy and pleasant work to get good pictures with a detective camera."

(o) "I would suggest that the bellows of the camera should be made of longer draw, so that objects less than eight feet could be photographed readily, and perhaps some copying done. The shutters on most detective cameras do not have the proper shaped opening, and I think that a shutter which works between the lenses is preferable to most of the shutters now used. I would also suggest that the lenses should be of longer focus than are generally used, say 7½-inch equivalent focus for a 4 × 5 plate. The ways on which my camera slides are made of soft wood, which in summer swell and make focussing almost impossible. If these were made of brass the camera would work easier."

(p) "Some invention to enable one to take many pictures without having to change plates or films, to avoid the weight of glass and yet not have the complication and expense of the roll holder. I think the celluloid film and the promised contrivance for carrying the same in one holder to the extent of about four dozen films will solve the problem."

(q) "If the future of plates is to be the ivory film, we want a case holding, say, twelve films, separated by, say, ferrotype sheets, so that a spring may push one at a time up into focus and make a dozen exposures at once. With all my admiration for the detective, and after three years' use of the same camera, I am the more convinced that instantaneous work is only an episode in the work of the amateur photographer. Time pictures are the cream of the camera, and however careful to focus with the detective, there is that difference between the two kinds of work which adds to the richness and depth of the time picture."

(r) "Dispensing with all clap-trap attachments. Less bulk and weight."

(s) "A camera in which can be carried films or other flexible plates without the necessity of independent plate holders, where no stripping would be necessary, would be the most desirable feature of any improvement that I could suggest."

(t) "A lens which would remove any necessity of taking any focus. Guessing at your focus is very unsatisfactory in my experience, and it is very inconvenient to have to go through the operations necessary to look through your ground glass and take an accurate focus. The plate on which the handle of my focus works is marked 6 to 10, 60 feet, and experience enables me to be pretty accurate, but I have found several pictures ruined by being out of focus when I guessed at the distance being about 25 or 30 feet. I saw an English (?) lens this summer that entirely obviated this difficulty. Any object at a distance of 10 feet was in perfect focus, likewise any object at a distance of 100 feet or more. This seems to me to be the chief fault and annoyance of a detective camera. I think also an arrangement by which you could carry more than three plate holders in your box would be a great improvement. I can carry but six plates in my box, and any carried in any other way run the risk of being injured unless one gives one's undivided attention to them. I ruined many such this summer in going off for the day, when I wanted to take many pictures and carried ten or twelve plate holders in a bag. Of course it would add somewhat to weight of camera box, but I should think six plate holders might be carried without inconvenience."

(u) "Not having any experience with the commercial varieties, I can only state what I find desirable and have adopted in my own models. The box should be light, rigid, and strong. All parts to be easily accessible with a key. At least one dozen—six holders—plates to be carried in the box. The front of the box to have a hard rubber shutter or cap, properly speaking, which covers both lens and finder, and by one movement uncaps both, so that whenever you see an image on the ground glass of finder you may be sure the large lens is exposed. For the vertical finder I have a separate cap, but as this is seldom used, the habit of moving the large rubber cap is not forgotten. Front of box to hinge and lock, allowing tension of shutter to be adjusted, if necessary, for slow work. Top of box provided with handle—leather. In front to have a piece of plate glass, hinged, and closing level over pointer attached

to lens shutter. Glass to be marked off with a diamond scratch into distances for 10, 15, 20, 30, 40 feet focus. Ground glass of horizontal slider to be at side, and protected from direct light by hood, right-hand side. The thumbscrew for moving by rack and pinion, the shutter and lens to be bevelled. Door, running the length of bottom of box, provided with lock to compartment for storing extra holders. Small door, with lock, for the introduction and withdrawal of holder at back of camera; vertical slider. Back, locked door, width of box, for focussing when required. Left-hand side perfectly plain. Bottom string release to shutter."

(e) "The shutter can be set and the diaphragm rotated through plate glass opening on top of box. A vertical pointer is screwed into centre of shutter, and work smoothly beneath the glass. The exact distance for which the lens is in focus is thus always indicated, and permits of the focus being rapidly changed without disturbing the position of the box while viewing the object in the finder. The centre part of each plate is marked on the finder, which is a great convenience. The rack and pinion have a movement of one and a quarter inch, so that a great range of focus is provided for."

(w) "That the focus be so arranged as to permit the use of the longest and shortest lenses adaptable to the size of the plate, and to be quickly adjusted from the outside. A lens mount adjustable for moderately narrow and wide angles. Some manner of hood or cover over the aperture in front of the camera, and be arranged to work automatically with the shutter as well as independently of it. It is presumable that all that one can suggest as real improvements have already been achieved by some one, and were all the best in one and the same camera it would leave little to be desired; but, unfortunately, cameras, like other appliances, have patents upon them, and different stock houses have control of the excellencies."

(c) "1st. Better mode of concealment than anything now in the market. In fact, I know of no detective camera that cannot be detected on sight—would recommend a satchel as mode of concealment, but not of as cumbersome a pattern as the one now sold by one of our stock houses. 2nd. Means of removing the camera proper from the box or place of concealment without loss of time for the purpose of mounting it on a tripod for landscape work. 3rd. Arrangement for changing lenses without loss of time and attracting attention. 4th. Rotary stops for the lenses and for instantaneous exposures. 5th. Larger finders, with lenses to correspond with the increased size of the finders. 6th. Swing back, so adjusted as to swing from the centre of the vertical side of the ground glass frame."

(v) "The general fault that I have found in detective cameras is the fact that the lenses do not cover with large opening the plate called for, and in consequence it is difficult to obtain a fully exposed plate of any subject, except in very bright light. If, however, a much larger lens than was necessary was used you could open it fully and have a finely cut and fully exposed plate, and be able to take an object much further off in consequence of the focal length of the lens being longer. Of course this would necessitate the box being made a little longer; but what I think desirable is that the result would be much better. The most interesting objects for the detective box are studies of everyday life, and as in many cases they keep pretty well in the shade, &c., the foregoing remarks are made applicable."

(i) "I would suggest some simple means of carrying quite a number of plates, and some device for changing them conveniently in the open air. In this way a large number of plates could be carried with but few plate holders."

(m) "The different parts requiring attention, focus, time, &c., are too scattered; they should, if possible, be so placed that they can all be seen at a glance."

(b) "Should I ever build another for my own use, I would put in two shutters—one having a range from 1/100th of a second upward would be placed between the lenses; the other, with, if possible, a range from 1/100th downward to say 1/10th, would be placed in front of the lens, and act also as a hood. What is wanted more than anything else is a plate holder for the new films capable of carrying a quantity (two or three dozen) in small space, and some arrangement whereby they can be quickly changed."

In the foregoing, the names of the various respondents to Mr. Duffield's queries are not given, as, with one or two exceptions, they are unknown to English readers; but they comprise some exceedingly able and clever workers, who occupy leading positions in several of the societies of the United States.

DAQUERRETYPE.

[A Communication to the Birmingham Photographic Society.]

It is instructive to trace the progress of a discovery from the first indication of the truth to the period of its full development and of its application to purposes of ornament or utility.

The progress of discovery is ordinarily a slow process, and it often happens that a great fact is allowed to lie dormant for years or for ages which, when eventually revived, is found to render a fine interpretation of some of Nature's harmonious phenomena and to minister to the wants or the pleasures of existence. Photography is peculiarly illustrative of this position. As in this year of grace, 1880, we celebrate the Jubilee of our art-science, it has seemed to me to be a suitable occasion to trace briefly the steps by which we have advanced to our present knowledge.

The progress has been slow and laborious, but it has been steady. And while we rejoice in the perfection of our apparatus, in our instantaneous plates and rapid lenses, in our ability to depict every phase of nature and art, from the bullet in its rapid flight to the mapping of stars which must ever remain unseen by the human eye, we ought never to forget the men who laid the foundations of all this. In asking your special attention to-night to the elegant process devised fifty years ago by the great Frenchman, Daguerre, I shall also briefly mention the work of other men who aided in the birth of photography, the infant of fifty years ago, the giant of to-day.

The philosophers of antiquity appear to have had their attention excited by many of the more striking effects of light, yet we have no account of their having observed any of its chemical influences, although its action on coloured bodies—deepening the colour in some cases and discharging it in others—must have been of everyday occurrence. The only facts which they have recorded are that some precious stones, particularly the amethyst and the opal, lost their sparkle by prolonged exposure to the rays of the sun. It has been stated, but on doubtful authority, that the jinglers of India were for many ages in possession of a secret process by which they were enabled in a brief space to copy the profile of any individual by the action of light. However this may have been, it does not appear that they know anything of such a process in the present day. The alchemists, amidst the multiplicity of their manipulatory processes in their vain search for the philosopher's stone and the *elixir vite*, stumbled upon a peculiar combination of silver with chlorine, an element unknown to them, which they called horn silver, as, by fusion, the white powder they obtained by precipitation was converted into a horn-like substance. They observed that this horn silver was blackened by light, and as they taught that silver only differed from gold in being mercury interpenetrated by the sulphurous principle of the sun's rays, they concluded that this change was the commencement of the process by which their dreams were to be realised. Failing, however, to produce gold from horn silver, the fact of its blackening was simply recorded, and no further investigations were made into this remarkable phenomenon. The illustrious Schéele, in his admirable *Traité de l'Air de Feu*, gave us the first philosophical examination of this peculiar change in the salts of silver, and showed the dissimilar powers of the different rays of light in effecting this change. In 1801, Ritter proved the existence of rays a considerable distance beyond the blue end of the visible spectrum, which had the property of speedily blackening chloride of silver. These researches excited the attention of the scientific world. M. Bérard, Seebeck, Berthollet, and others, directed their attention to the peculiar condition of the different rays in relation to their luminous and chemical influences; while Sir William Herschel and Sir Henry Englefield investigated the calorific powers of the coloured rays, and were followed in these investigations by Seebeck and Wunsh. Dr. Wollaston pursued and published an interesting series of experiments on the decomposition effected by light on gum guaiacum. He found that paper washed with a solution of this gum in spirits of wine had its yellow colour rapidly changed to green by the violet rays, while the red rays had the property of restoring the yellow hue. Sir Humphry Davy observed that the puce-coloured oxide of lead became, when moistened, red by exposure to the red ray, and black when exposed to the violet ray; that hydrogen and chlorine entered into combination more rapidly in the violet than in the red rays; and that the green oxide of mercury, although not changed by the most refrangible rays, speedily became red in the least refrangible. The revival of gold and silver from their oxides by the action of the sun's light also occupied the attention of Count Rumford, who communicated two papers on this subject to the Royal Society. These and some curious observations by Morichini, Confalachi, M. Bérard, and Mrs. Somerville, on the power of the violet rays to induce magnetism in steel needles, are the principal points of discovery in this branch of science previously to the announcement of the Daguerreotype.

A statement has been made by the French to the effect that M. Charles was in possession, about the year 1790, of a process by which portraits could be obtained by the agency of sunlight producing a dark impression upon a prepared surface. This is, however, exceedingly doubtful; and even the Abbé Moigno, in his *Repertoir*, states that M. Charles never disclosed any fact connected with his hypothetical discovery, and that he left no evidence behind him of ever being in possession of such a secret process.

In June, 1802, Mr. Thomas Wedgwood, a son of the celebrated porcelain manufacturer, published, in the *Journals of the Royal Institution, An Account of a Method of Copying Paintings upon Glass, and of Making Profiles by the Agency of Light upon Nitrate of Silver, with Observations by H. Davy*. This was certainly the first published account of any attempt to produce images by the decomposing powers of light. Mr. Wedgwood made use of white paper or white leather moistened with a solution of nitrate of silver. He found that white paper or white leather moistened with a solution of nitrate of silver underwent no change when kept in a dark place, but on being exposed to the daylight it speedily changes colour, and, after passing through different shades of grey and brown, becomes at length nearly black. When the shadow of any figure is thrown upon the prepared surface the part concealed by it remains white and the other parts speedily become dark. The images formed by means of the camera obscura were found to be too faint to produce in any moderate time an effect upon the nitrate of silver. Davy made some important additions to Wedgwood's work. He found that the chloride was much more sensitive to light than the nitrate of silver. Both Wedgwood and Davy attempted to secure the pictures formed within a camera upon paper coated with these salts of silver, but without success. Davy, however, using the more concentrated light of the solar microscope, readily obtained images of small objects upon paper prepared with silver chloride. But there was a fatal objection to this method which not even Davy, with all his chemical knowledge, was able to surmount. When the copies obtained were exposed to daylight the same agency which had produced the picture proceeded to destroy it. Davy clearly recognised its capabilities, for he writes:—"Nothing but a method of preventing the unshaded parts of the delineations from being coloured by exposure to the day is wanting to render this process as useful as it is elegant." In this copying process, devised by Wedgwood and improved by Davy, we see the germ of the ordinary method by which our negative photographs on glass are made to yield a positive proof or impression upon sensitized paper.

(To be continued.)

W. THOMAS HORTON.

HYDROQUINONE.

[Discussion on Mr. T. Charters White's paper at the Camera Club. See page 124.]

Mr. MASKELL said: I should like to bring under the notice of the meeting a formula for hydroquinone development with which I have obtained very satisfactory results. It is one which I obtained in Paris last September from M. Mercier, a chemist in the Faubourg Montmartre. It is very simple, consisting of four hundred grains of carbonate of soda, three hundred and sixty grains of sulphite of soda, and forty grains of hydroquinone; no bromide. Though somewhat prejudiced at first, I was entirely converted to the use of

by hydroquinone during my visit to Paris. Whether or no in the hands of the most experienced workers superior results might not be obtained by the pyro process, especially with difficult subjects, I am not prepared to say, but I am convinced that for the ordinary amateur, even of considerable experience, much more uniform and satisfactory results will be obtained. With pyro and ammonia, or pyro potash, how many amateurs could be trusted to obtain equal and good results from the exposure of two plates on the same subject and with the same light, giving to one plate one second and to the other twenty seconds' exposure? Yet I hold that this can be done with ease by the proper use of the hydroquinone bath. This developer has the advantages, amongst others, of permitting great latitude of exposure, of being cleanly, not staining the fingers, of affording an easy and regular development, of obviating the necessity of continuous rocking of the dish, and of cheapness, as I shall endeavour to show. It may, indeed, be said to be almost automatic in its action. The great latitude of exposure permitted is surprising, and this is counteracted by the use of new or used baths. That is, indeed, the whole secret of the certain success which may be obtained: for instantaneous exposure a new bath; for prolonged exposure an old one. It is my practice to keep a number of three-ounce bottles with developers of varying degrees of age or use; on each I note the number of plates for which the contents have served; I keep them filled to the stopper, which preserves the contents from alteration. If I am uncertain of the exposure a plate has received, I place it in an old bath, and if at the end of three or four minutes nothing comes up, I try a newer one, and so on. It is not difficult to judge, nor is this process so tedious as might be imagined. Great cleanliness of materials and dishes is essential, and the developer should be filtered after use. No pyro, iron, or hypo should come near it. The dish need not be rocked, neither is the plate stained as with pyro, if the developer does not flow over evenly at once. If, as I admit, the development is sometimes very prolonged, never mind; cover up the dish, leave it to itself for half an hour or an hour, which you can employ in other ways. You can develop twenty or more plates at a time, especially if you use a grooved dipping bath, and allow a short interval between placing each plate successively in the bath. By these means you have them under perfect control. It is cheap, because the same bath can be used so many times. I lately developed eighteen lantern slides with the same three ounces of developer, the last as easily as the first. Thomas's hydroquinone developer is sold at 3s. for two pints; you can make the two pints for about 1s., say ten ounces for 3d., which would develop at least twenty-four lantern plates and be still serviceable, say two plates for a farthing. Removing the plate from the developer at intervals, and allowing it to remain in a dry dish is good; raising the temperature also is good, for under-exposed plates especially. Hydroquinone is a good and clean developer for bromide and Alpha papers, and I should say the very best for lantern slides, less troublesome than ferrous oxalate, to prepare, to use, or to keep. If you wish to utilise your old baths give prolonged exposures. Fogging is rare; almost impossible. I remember in my early experiences of photography, my plates often veiled over very quickly; now, with an unexperienced hand the plates can go into the hypo with the shadows and rebates bright and pure. I prefer myself that they should be slightly veiled over, the results are softer. I intended to show two lantern slides for information concerning the difference of tint; but I have unfortunately forgotten to bring them: one was a good black, the other pink. It seems to me there are four factors, or conditions, to be considered in the production of different tints; that is, long exposure with new or old bath, and short exposure with a new or old bath. But I do not know how to regulate the conditions of tint. I think that hydroquinone is a step in advance towards the realisation of a perfect automatic developer. The idea may be ridiculed for the moment, but I can quite conceive the time arriving when the question of exposure may become (within limits) almost a negligible quantity. That is to say, that (within limits) given any exposure, short or long, a reagent may be found which will automatically bring out, with correct and proper gradations, all that the light has impressed on the sensitive surface. When that time arrives it will be a triumph of chemistry, but I venture to say that a great deal of the interest of development will be gone.

Mr. ELDER said that he did not think, in spite of Dr. Elder, that resorcin could be used as a developer, for he had tried it, and it had failed to produce any image on the plate; however, he meant to try it again. Pyrocatechin, the other isomer of hydroquinone, had been used successfully, but its price, 5s. a drachm, was an almost insuperable bar to its use. No doubt, however, if a demand arose for it, it would be reduced. With regard to Mr. Charters White's statement, that he had found a greenish-brown deposit in the hypo bath, it was possible that that might be green hydroquinone—a very beautiful crystalline body formed when hydroquinone in solution is carefully oxydised, e.g., by ferric chloride. Lately a great deal had been said about the use of caustic soda or potash instead of the carbonates of these alkalies with hydroquinone. Four years ago the speaker had found the advantage of using these alkalies in the developer; however, he had supposed that it was well known, and had not thought it worth publishing except in a letter to the maker of the plates he was then using. He was rather surprised to find the use of these alkalies recommended as something new. With caustic alkalies hydroquinone was a first-rate developer for positives, whether on paper or glass, but it was not so good as pyro for negatives.

Mr. WILSON NOBLE spoke strongly in favour of hydroquinone for developing bromide papers. He found no tanning action, acid and alum were not needed, and there were no blisters. The colour, too, was better than with ferrous oxalate. With ferrous oxalate the deeper shadows appeared to come first, and so on to

the half tones, but with hydroquinone all the detail appeared to come together, and then to gather density without fogging. He had kept the developer standing three days, and found little or no difference in using it.

Mr. LYONEL CLARK said he was sufficiently conservative to still refuse to believe that hydroquinone would oust their old friend pyro. In France it had certainly made very great and considerable advances, but there it had a much feebler enemy to contend with, for, as every one knew, ferrous oxalate was the favourite developer on the Continent. And his remarks that evening would be on hydroquinone as a substitute for ferrous oxalate, and especially for the development of bromide prints. He had tried a good many experiments on bromide papers with varying proportions of hydroquinone. Considering that it is an undoubted advantage, if equal results can be obtained, to use a quick development, he had confined his experiments to the use of the hydrates, or, as they are more commonly called, the caustic alkalies. The first point he had ascertained was that, in order to get best results, exposure should be, for an average negative, about four times as long as would be given if ferrous oxalate were used. This was the keynote of the whole affair, and showed the immense advantage that hydroquinone possessed. The great difficulty in ferrous oxalate development has always been that if the negative were at all dense, and sufficient exposure were given to enable the light to act through that deposit, on development the shadows would be bunged up before the detail in the high lights showed. Although not an impossibility, it was a most difficult thing to get a satisfactory print from a hard negative when using ferrous oxalate. With hydroquinone, on the contrary, if this salt be kept down, it is perfectly possible to bring out all the detail first and then gradually allow density to gather. He had found that about two grains of hydroquinone gave very good results when the salt had twice its weight of meta-bisulphite, or eight times its weight of sulphite added as a preservative. The alkali used was caustic potash, the ordinary K₂CO₃. Hydric. Dep. of commerce; about five to six grains per ounce appeared to give good results, but, like the alkali in a pyro developer, it can be added gradually and as required. With a developer as above described, up to twelve grains of potash could be used, but when this amount was added, black blotches began to be formed in the shadows. He (the speaker) was inclined to put this down to the corrosive action of the caustic alkalies on all animal matter, such as gelatine, and thought an explanation of the phenomenon shown by Mr. Elder to be due to the same cause. The effect of lessening the quantity of hydroquinone was to make the colour of the deposit of a brownish colour, and also to slow the development. This was a very noticeable fact: below a certain point any increase in the quantity of hydroquinone considerably quickened development, although no further alkali was added. In fact, with normal exposure it was almost impossible to get anything but a shadow when less than one grain of hydroquinone was used. One point in development of bromide paper was the uneven way in which the image appeared. Commencing usually at the edges, they darkened up rapidly to full intensity, and it was some time before the centre would follow suit. However, on completion no signs of unequal deposit were shown. He would also hand round a few specimens of Alpha paper developed by this salt. The colour was very rich and pleasing, and varied from a reddish to a rich brown directly as the amount of hydroquinone present, and he considered that it would be most valuable for use with this paper. In conclusion, Mr. Maskell had mentioned Mr. Balagny's claim that hydroquinone was an automatic developer, and had further expressed a hope that in the millennium of photography we should have a developer that would develop all exposures. If such was to be the millennium, he (the speaker) thought it would be as great a failure as a good many other hoped-for millenniums; and if such a developer did exist, he should be sorry to have to use it. He considered the great point in all development was that we could integrate its composition, and obtain any desired results, and he advocated hydroquinone in preference to ferrous oxalate, for the sole reason that it was "tentative" in its action and non-automatic.

Mr. DAVISON said there was very strong staining and tanning action with hydroquinone if it were allowed to act long. He did not agree with Mr. Maskell as to the use of old baths, as the state of energy of these was not known. He recommended the use of hydroquinone for lantern-slide work, and also particularly for developing Alpha paper.

FIFTY YEARS' PHOTOGRAPHY.*

In 1843, Herschel published a process whereby what are known as breath pictures were produced. It would be most interesting to reproduce many of these early results. We could have plenty of material for our meetings if some enthusiastic member were to take up some of these bygone methods and show them to our members. The suggestiveness of all the work which Herschel did in this way is only known to those who have taken the trouble to go into the literature of the subject; but we must hurry on. It just remains for us to say, that Herschel *secundus* died in the year 1871, on the 11th of May, at Collingwood. He was born in the year 1792, and was, at the time of his death, close on eighty years old. The nation, in giving him a place among the great men interred in Westminster Abbey, have shown their appreciation of his worth. His remains have been deposited close to those of Sir Isaac Newton. The biography of Sir John Frederick William Herschel has yet to be written. The same applies to the father, Sir William Herschel.

* Concluded from page 145.

The action of light on bichromates, in presence of organic matter, is the basis of carbon printing, Woodburytype, collotype, and analogous processes. The fact that light could impress an image on paper saturated with a solution of bichromate of potash had been known for a considerable period before anything practical resulted from it. The name that has been associated with the reaction indicated, is that of Mungo Ponton, and, curiously enough, the year 1839 saw this announcement also.

Another early worker, and one who has just recently passed away, was Robert Hunt, his death occurring in the year 1887. Born in 1807, he had reached the ripe age of eighty. I regret I am unable to show his portrait. A record of his experimental work is to be found in his *Researches on Light*, the first edition of which was published in 1844, and this was followed by a subsequent edition in 1854, containing almost as much as double the amount of matter contained in the original. He was a voluminous writer in his day, but it would extend this communication to an undue length were we to particularise these. Hunt was the first to draw attention to the use of sulphate of iron as a developer, and this was as far back as the year 1844. As you are aware, in the collodion process this chemical is employed to the present day. In his experiments the action of the solar spectrum on silver salts, with or without admixture of other substances, was fully gone into. It may interest members to know that at the first meeting of the first photographic society in Glasgow, on March 8, 1851, Hunt was present and addressed the meeting. Though we may call ourselves the heirs of that Society, still we are not the true descendants. The Glasgow Photographic Association can date from 1862, seeing it was only a revival of the older Photographic Society of Glasgow. At the meeting in question, Jabez Hughes read a paper on *The Prospects and Progress of Photography*. At that time Hughes had his studio in Glasgow, and Sheriff Bell was the chairman of the evening.

To return to Hunt. From a photographic point of view we think it unfortunate that an original investigator such as he did not remain true to his first love. He drifted, ultimately, into a different scientific channel altogether. He was a geologist as well as a photographer, and as he received the appointment of "Keeper of Mining Records," the work of his later years lay in quite an opposite direction. He edited *Ure's Dictionary of Arts and Mines*, and his latest work was *British Mining*, published in 1884. Hunt was a member of the Royal Society. To those of our members who may wish to get suggestive material for new processes and new reactions, we know of no treatise or treatises which can compare with Hunt's *Researches on Light*.

We will now cross the channel and see what was being done in France by two men whose names are now a record of the past, Abel Niépce de St. Victor and Edmund Becquerel. Niépce the younger, as he has been called, was not, as generally recorded, Nicéphore Niépce's nephew, but the son of a nephew, Bernard Niépce. Niépce de St. Victor was a soldier, but studied chemistry, and inspired no doubt by what Niépce the elder had done, busied himself with photographic matters. In 1847, he presented to the French Academy a memoir of a process in which starch spread on glass holding the silver salts was made use of. In 1848, he announced the albumen process, in which the starch was replaced by the white of eggs. Niépce de St. Victor is usually credited with being the first to use glass, but I think this honour should be given to Herschel, as already pointed out. Niépce de St. Victor worked hard at the still unsolved problem of heliochromy, or photography in natural colours. A certain amount of success attended his efforts, and I believe specimens of results obtained are to be seen at South Kensington; however, as these experiments for the most part refer to a period beyond that at which I shall have to close this communication, we shall rather pass on and consider the work of Edmund Becquerel, which dates from the year 1848. Niépce de St. Victor died on April 6, 1870.

Becquerel was a French physicist, and his father, Antoine Cesar Becquerel, was also a man famous for his scientific researches, which were chiefly electrical. Becquerel the younger, on February 7, 1848, presented a memoir to the French Academy of Sciences on the coloured photographic image of the solar spectrum. He experimented with Daguerreotype plates, and by means of a layer of chloride, or, rather, what is known chemically as a subchloride, he was able to reproduce in a more or less perfect manner the colours of the spectrum which had been allowed to fall on the plate. Another memoir was submitted in the following year, viz., 1849, and in this he gives full details as to the preparation of the colour sensitive chloride. His mode of preparing this was an electrical one, and consisted in placing the plate in a solution of hydrochloric acid, connecting it with the positive pole of two Bunsen cells. Opposite the silvered plate a platinum conductor of the same size was placed in solution, and the current in passing decomposed the acid, and the chlorine given off attached itself to the silver plate, giving the form of chloride susceptible to colour influence. We need not go further, but enough has been said to show how early in the day the search after colour photography took place. As the matter stands we are apparently no nearer the unsolved problem than in the time of Becquerel, notwithstanding the fact that succeeding workers have spent years of study and research on the subject. So far photography in natural colours has proved a veritable *ignis fatuus* to the photographic traveller. Is this to be the permanent state of affairs, and are we to accept the fact that the thing is impossible? I do not wish to be dogmatic, but taking it for granted that heliochromy were to-morrow an accomplished fact it could

not impress me more than does the fact that our photographic plate is now so susceptible to light radiations that an exposure amounting to only the fractional part of a second can give a picture. Would colour photography be one whit more wonderful than this everyday occurrence in our photographic work? Science, to my mind, has performed feats much more difficult of accomplishment, and seemingly more impossible than what this appears to be. Take the telephone; even the most sanguine electrician did not conceive it possible that speech could be reproduced at the end of a wire miles apart from where the original words were delivered. Take the phonograph; what could be more wonderful, or even more weird, than the fact that we are enabled to put away the tones and voice of a human being, and reproduce them, it may be years afterwards, when the speaker has been called to his fathers, and the voice is hushed for ever!

In conclusion, we should refer to Dr. John William Draper, the famous American, and his photographic work. I purpose, however, breaking off at this point, and will leave the consideration of what he did to another occasion, when I shall be able to show his portrait by means of the lantern.

W. LANG, JUN.

HYDROQUINONE AS A DEVELOPING AGENT.*

CLOSELY bound up with the quality of energy is that which I mentioned as coming next after energy in importance, but which, in reality, is inseparable from it—namely, the property of only acting where the light has acted. It is a very great merit in a developer to develop cleanly—to only take notice of that provocation to action which the impact of light originates.

We all know that it is a weakness of some developers, especially those of an energetic kind, not to discriminate between the effect of light and the effect of various malefic influences which tend to what is called fog; and it is undoubtedly an element of great advantage in a developer if it refuses to recognise those fog-producing tendencies, and only pays respect to the disturbance set up by light. I claim for quinol this quality in a very high degree; in fact, I think it far excels all other strong developers in this respect.

In proof of this I pass round two negatives, they are both produced on the same plate (No. 3), which was cut in two. Equal exposures were given to the two halves, and one was developed with pyro and ammonia, and the other with quinol. The negative developed by pyro shows, on the margin entirely protected from the light, and in all the deep shades, a strong fog—copper colour by reflected light, and violet by transmitted light. The other negative—that developed by quinol—is perfectly clean, the chemical action being, in it, restricted entirely to the parts affected by light. It is, in fact, a perfectly good negative, particularly clean in the non-lighted parts, and this difference is not due to a difference of energy in the two developers used, for the quinone developed image has quite as much of the true effect of light brought out in it as the fogged image developed by pyrogallol.

I send round a second illustration of this point (No. 4), but showing the difference in the effect of pyro and quinol on a plate with a strong tendency to fog of another kind, namely, to surface fog, that very troublesome kind of fog which some plates are liable to, and which generally manifests itself after plates have been kept a long time, and have been acted upon by air.

In the plate developed by pyro, this kind of iridescent fog is seen very unpleasantly. It mars the negative a good deal, but does not entirely spoil it. The other negative, cut from the same plate and developed with quinol, is absolutely free from any taint of fog of any kind—it is perfectly bright and clean. Now this property of quinol of not producing fog on plates which would ordinarily be foggy, is an exceedingly valuable one, and I desire to give strong emphasis to it. All things being equal, I think it is a very decisive ground for preference being given to quinol as a developing agent.

Before I pass on to another point, I will send round a very interesting negative, No. 5. It was produced a few days ago upon a plate coated on January 31, 1880. It was, therefore, nine years old before being used. It has been cut in two after exposure in the camera, and one half developed with pyro and the other with quinol; both halves are quite good, but the quinol half is much the cleaner and brighter of the two.

I now pass round two negatives marked 6 and 7, which show the effect of varying the proportion of bromide and of omitting it altogether. No. 2 you have already seen; it has the normal proportion of bromide in its developer, and should be compared side by side with the other two, one of which had more and the other less than the normal proportion of bromide in their developers. It will be observed that the effect of the bromide has been to slow the development and brighten the image. As these were all developed for the same time, namely, two and a quarter minutes, it is not

* Concluded from page 143

evident from this experiment whether the bromide only retards development or definitely enfeebles it. If more time had been given, possibly more detail in the shades would have been developed with the solution containing bromide. Here are another pair of negatives, marked 8 and 9. These illustrate the effect of varying the proportion of sulphite of soda, and they are particularly interesting. They show the immense effect of sulphite of soda on density and colour. Mr. Green says with regard to this that "Sulphite plays a most important part in quinol development. Its efficacy in preventing discolouration is, I think, very well understood, but I have not observed that any attention has been drawn to one of its principal features, namely, its influence upon density. A comparison of 2, 8, and 9 will show how essential it is that this should be thoroughly understood, and the importance of using only the purest samples of sulphite soda."

This property of sulphite of soda in the quinol developer provides a means of compensating for over exposure by varying the proportion, using, to begin with, as little as will suffice to prevent stain.

While I am speaking of sulphite of soda, I may as well also speak of meta-bisulphite of potash. Meta-bisulphite cannot be substituted for sulphite with good effect in a quinol developer. It has not the same virtue in connexion with quinol that it certainly has in connexion with pyro.

It has a great preservative action upon quinol by undoing the effect of oxidation, which is to produce quinone, but unless used very sparingly indeed it destroys the developing effect of quinol almost entirely. See negatives 10 and 11.

I now come to my last series of negatives, marked 12, 13, 14, 15, and 16. They illustrate, comparatively, the effect of potash and soda in the caustic state, and in the state of carbonate. In this set the development was continued during three minutes instead of (as in the case of all the other negatives except the actinometer negatives) two and a quarter minutes. With this exception, you will understand that all the plates I have shown were alike to begin with, and that they were all exposed for the same time.

This series, 12, 13, 14, 15, and 16, shows clearly the superiority of caustic potash as a stimulant to development. The feebleness of carbonate of soda relatively to carbonate of potash (used in equivalent proportions) is remarkable. It is possible that this may in some measure be due to a difference in the action of the citrate of soda formed in the one developer and the citrate of potash in the other, and that in the absence of citric acid as an ingredient in the developing solution the same difference in the action of the two carbonates might not have existed.

There does not appear to be any marked inferiority in the extent to which detail is brought out in the faintly lighted parts by the carbonate of potash as compared with caustic potash, although there is a great difference both in the colour and the strength of the image. On the whole, preference will probably be given to caustic potash. With regard to a definite formula for a quinol developer, I may say that Mr. Green has made innumerable experiments with a view to arrive at a formula that would most generally meet the wants of the photographer in the studio and in the field, that would give a fine quality of image a good colour, and develop in the same time as pyro and ammonia. The result of these experiments is the following formula:—

A.
Hydroquinone (quinol) 80 grains.
Citric acid 10 "
Sulphite of soda (recrystallised) 80 "
Distilled water 20 ounces.

B.
Caustic potash (fused) 160 grains.
Sulphite of soda (recrystallised) 160 "
Distilled water 20 ounces.

C.
Bromide of potassium 24 grains.
Distilled water 1 ounce.

D.
Caustic potash (fused) 160 grains.
Distilled water 20 ounces.

Fixing solution:—Hyposulphite of soda, 1lb.; water, 40 ounces.

For normal exposures use equal parts of A and B, adding five minims of C for every ounce of solution.

For over-exposed plates use D instead of B, with an extra quantity of C.

For under-exposed plates, omit C, and, in extreme cases, add six

or eight grains more of sulphite of soda to every ounce of developer.

Plates showing a tendency to frill should be immersed for one minute in a five per cent. solution of common alum between development and fixing; washing before and afterwards.

Note.—The object of decreasing or increasing the quantity of sulphite is to give greater or less density.

Gentlemen, I have spoken of several of the advantages of quinol as a developing agent, but I have not spoken of all. I have said nothing of the advantage of getting rid of the fumes of ammonia in the dark room, nor of the greatly less tendency of quinol than pyro to stain the film during protracted development. I have not mentioned the development of positives on gelatino-bromide paper nor of diapositives for the magic lantern, although I have examples here which show the excellence of quinol for these purposes, but I hope I have said enough and shown enough to lead those of you who have not yet tried quinol as a developing agent to give it a fair trial.

J. WILSON SWAN, M.A.

THE DETECTION OF BRONZE POWDER ON MOUNTS.

THE time is past when it was needful to warn photographers to beware of the insidious pest, bronze powder, or mosaic gold; but a few words on its detection may still be found useful.

Some time ago I heard of a photographer who was in great distress because all the prints that he sent out became spotty within a few months. He tried all the remedies he could think of without avail. He washed his prints for an unreasonable length of time, and tried all sorts of mounting materials, but the evil was in no way decreased. As his mounts were printed in brown, and had no trace of gilding about them, it did not seem at all reasonable to suppose that bronze powder could be the cause of all the trouble. And yet such was the case. One of the mounts was sent to me for examination. I may here remark that the uninitiated have a very touching faith in the powers of the analytical chemist. A zoologist once showed me some tiny white granules which he had found inside some beast; perhaps there was altogether half a grain or so of material. These granules, he explained to me, consisted of an outer and an inner layer of different structure. He wanted them analysed, and could not I contrive to analyse the two layers separately? This by the way. The problem in the present case did not prove quite so hard, though the quantity of material to be dealt with was probably very much smaller than that which my friend the zoologist placed at my disposal. The most careful inspection with the naked eye revealed nothing, but patient search with a lens of high magnifying power (perhaps about twenty-five diameters) revealed a few minute spots of a coppery, metallic lustre. So very small were these specks that, even after they had been seen, it was far from easy to discover one again unless a mark was made to indicate its position. From their appearance it was obvious that these spots must consist either of leaf metal or mosaic gold. They were first treated with hydrochloric, and then with nitric acid, both as strong as could be applied to paper without rapidly disintegrating it. As the spots remained unaffected they were evidently not Dutch metal, which would have dissolved readily. A globule of mercury was next rubbed over the part of the mount which had been treated with acid, but the metallic specks remained unchanged. Gold would have amalgamated, and either disappeared or turned white. These tests practically exclude everything except bronze powder, but for further confirmation a drop of sulphide of ammonium was applied, and it was found that the spots very slowly disappeared, thus proving that they consisted of sulphide of tin. The bronze powder in this case had probably come from the press used in printing the mounts, which may have been used for stamping in gold previously. This obnoxious substance is so light, and clings with such pertinacity to any support, that once it has been introduced among any photographic materials I should say there is no remedy but to destroy the lot. As a preventive measure, I would say that presses used for stamping photographic mounts should never be employed for printing in gold.

Why sulphide of tin or bronze powder should destroy prints it is not easy to say, but perhaps the following is an explanation of the action. The sulphide may be very slowly oxidised, being converted into oxide of tin, sulphur being set free. This latter might then also be slowly oxidised, forming sulphurous, and eventually sulphuric acid, which would attack the metal of the image.

Whatever the explanation may be, the evil is a very real and great one, and I hope that the above remarks may give some assistance to photographers in their efforts to detect and banish the enemy.

C. I. BURTON, B.Sc., F.C.S., F.R.S.E.

ON DETECTIVE OR HAND CAMERAS.

As many readers may be contemplating the working of "detective cameras" during the coming season, and may wonder how they act, a few words from an old hand may be of some little service, and knowing the urbanity of our worthy editor, I will venture to give my experience, not, however, without a certain amount of reluctance, as some readers will in all probability have views different to mine; but, after all, there will be nothing new in this, as there is diversity of opinion in all things, and none more so than in the camp of photography. It is well such is the case, or else our existence would become monotonous; uniformity would create weariness, healthy competition would be gone, and our photographic literature would become defunct.

Finders.—I have observed among some amateurs a tendency to discard this—I consider—very necessary instrument, and I fear, in the majority of cases, dispensing with it means an increased production of unsatisfactory work, unless plates of larger dimensions are used than is intended to be shown in the trimmed prints produced from the negatives, as it would be almost impossible to get the picture properly centred. The result necessarily must be, in the majority of exposures, either too much or too little foreground, or the absence of that nice adjustment or balancing of parts which conduce to the production of true artistic effect, and which it would be impossible to judge of without seeing it first reflected in the finder. Who does not know the change in the composition of a picture by moving from any given position, even a few feet? In fact, such a method of procedure, to my mind, resembles a sportsman, who, at the moment he should be sighting his gun, shuts his eyes and takes a random shot. Granted then the finder is requisite, first carefully examine it and see it represents identically the same extent of view as the lens shows on the negative, using a piece of ground glass in the dark slide for that purpose in the usual manner, and should it—the finder—be found to embrace a more extensive view than is produced on the negative, carefully block out the excess.

A true vertical line ruled somewhere about the middle of the finder, and another placed horizontally about one-third from the base of the picture, will be found of considerable service, as the former, with the assistance of the outside edges, will ensure an upright picture, and there are always some leading features present which will enable this to be effectually carried out. The latter will be found serviceable for such subjects as shipping, or any other where the horizon line should be kept perfectly straight.

In taking street views or scenes in which there are many moving objects, avoid "firing" when conveyances or other prominent objects are traversing across the picture, or the result will be disappointing. Objects moving obliquely or parallel with the lens can generally be secured perfectly sharp, even with the shutter working at what might comparatively be described as slow speed. When you consider the grouping is satisfactory, again turn your attention without loss of time to the finder, observe the buildings are in true vertical position, with the assistance of the lines indicated, and granted you have not overlooked that sufficient foreground is included, "fire," but not before you are certain the camera is steady.

In this manner, after a little practice, you can secure a much larger proportion of successes than most workers, and it is much more gratifying on developing the fruits of your labour to find you have on the average about nine perfect results out of every ten exposures, all fit for enlargements, than it is to take chance shots, many of which would, but for some slight neglect, have made excellent pictures. I cannot sufficiently impress the advisability of keeping the camera perfectly steady at the time of setting off the shutter. Hold the camera with your left hand, preferably against your side, and on no account attempt to fire—however tempting the grouping may be—until you feel assured your body is perfectly still. Hurry to secure a subject you are not fully prepared for means certain failure.

We will now take up the question of the most suitable focus of lens for this special work. This is one on which much might be written. Both long and short foci have their special advantages, and having been accustomed to both, I have come to the conclusion that the shorter focus is the most suitable for those who can have but one camera, as there are several points in its favour, the principal ones being, the compactness of the apparatus—which most of us know how to appreciate—and, secondly, on account of the lens embracing a wider angle for a given size plate, and, consequently, greater suitability for embracing views of buildings of any magnitude, or street views, particularly those of limited dimensions, and most photographers know that frequently interesting pictures are to be obtained in such localities. For such work lenses of long foci would be practically useless. Although I have pleaded the claims of the shorter focus lens, the longer focus, under certain conditions, will give better re-

sults, but such are the exceptions, not the rule. The principal claim of the latter is its adaptability to secure groups in their natural positions, whether representing pleasure or toil, and the same remarks apply, as far as the grouping goes, to pastoral subjects—cattle, sheep, and such-like—as you have not to advance so closely as to draw special attention, and, therefore, owing to their being to some extent unconscious of your proximity, and, in the case of our fellow-creatures, of your manoeuvres, you obtain pictures which under other conditions would be almost impossible.

We will now touch on the question of focussing. Here and there we come across advocates of a "fixed focus;" true, every lens permanently fixed in a camera will give everything beyond a certain distance in focus, but more than this is desired by the vast majority of workers. Such advocates not only limit the scope of their lens, but absolutely forfeit many chances of admirable near-to subjects, and labour under other disadvantages of equal importance. In fact, they reverse the usual order of things, and give the operator the unnecessary trouble of focussing himself to suit the "fixed" ideas of the lens, instead of focussing the lens to suit his ideas and the view he would desire. I would strongly advise every one to have a camera that has a moveable focussing arrangement, and let him carefully mark various distances on the indicator, either himself or with the assistance of a friend, should he have any doubt about his ability to accurately decide where to make the marks. When testing, do not focus for the centre of the ground glass, but a little on one side, as a better all-over focus will be obtained, which will be apparent in the negatives. As for distances, start with, say, ten feet, then fifteen, twenty, thirty-five, mid-distance, and extreme distance. A little experience and occasional reference to the distances named will soon accustom the eye to accurately estimate them, and the cultivation of the faculty thus acquired will not be lost.

It would be a considerable advantage to the vast majority of photographers, and one that would be fully appreciated, if some means were devised which would simplify the method of reversing or changing the backs which carry the sensitive plates in "detective cameras," or, still better, if they were superseded and the plates changed without any troublesome manipulation. Those who are in the habit of practising this description of work are supposed to become indifferent to the scrutinising looks and remarks of bystanders, but it requires some tuition before the equanimity or assurance to change or reverse the dark slides under the public gaze can be acquired. In towns these drawbacks can, in a measure, be obviated by retiring to some secluded spot to effect the operation of changing. Seaside resorts are, however, most unfavourably situated in this respect. Here are to be found those seeking relaxation, sweetly enjoying the balmy breezes, or leisurely and aimlessly strolling about, who, having satiated their eyes with the natural surroundings of the neighbourhood, are on the alert for some trivial incident to enliven their curiosity. Having been discovered, you are at once an object of interest—to the juveniles a mystery. *Paterfamilias*, who on the seashore is to-day "secured" in some attitude conducive to the merriment of the youngsters, mysteriously develops a studied mien on your appearance on the morrow, having in the interval been taken into the confidence of one who considered it incumbent to convey the intelligence. To endeavour to secure negatives which might be described as "personal" is a system that deserves condemnation. The legitimate use of a "detective or hand camera" is to obtain views and groups, and not portraits of strangers, whose sense of propriety forbids them remonstrating with you—an unpleasant undertaking at best. Single figures, representing in varied characters labour and recreation, might be taken at all times. There is an endless number of subjects to be obtained in every direction without making the operator objectional. A little discretion is only requisite to get together a collection of negatives as miscellaneous in character as in interest.

In describing and recommending a short-focus lens as being in general the most useful, let it be understood that for a quarter-plate negative a five and a half inches equivalent focus is meant. Nemo.

ON THE VALUATION OF COMMERCIAL HYDROQUINONES.

[A Communication to the Photographic Club.]

You will no doubt recollect that at our last meeting I had the pleasure of informing you that I have, for some time past, been engaged in examining various samples of hydroquinone, with a view to establish some method enabling one to form an opinion as to the value of a given sample. I now beg to lay before the Club the results of my investigation, and I will deal more especially with two samples which were entrusted to me by members of this Club.

I had thought at first that hydroquinone, being essentially useful in photography, because of its reducing properties, the determination of the value of a given sample might be arrived at by endeavouring to find out what quantity of a standard solution of potassium permanganate would be decolourised by a weighed portion of the hydroquinone. I therefore proceeded to dissolve equal weights of both samples in water, to which a small quantity of sulphuric acid had been added. A titrated solution of permanganate was run into the solution, but I very soon found that there did not appear to be any satisfactory termination to the reaction. The final pink colour was obtained, but vanished soon, and could be reproduced at pleasure, vanishing again in approximately the same length of time as before. I think that this is mainly due to the fact that gradual oxidation transforms hydroquinone into quinone, and that the latter compound is not without action on the permanganate, especially in presence of the sulphuric acid, which is indispensable in the titration by permanganate. It is, of course, impossible to operate in an alkaline, or even neutral solutions, as these would darken so much through oxidation that the final rose tint of the permanganate would be obscured completely.

Schorlemmer says that by acting on hydroquinone by nitric acid, oxalic acid is produced, whereas quinone yields a mixture of oxalic and picric acids. It is not, however, stated whether one, two, or three molecules of oxalic acid are produced by this reaction, and if only one or two molecules, what the other products may be.

In order to ascertain whether the residue of the oxidation by nitric acid could be made use of as the starting-point of an analytical method, I weighed out a small quantity of each sample, and oxidised it with dilute nitric acid at first, and after evaporating it to dryness, it was twice thoroughly moistened with nitric acid, and evaporated to dryness each time. I must now allude to the two samples under consideration.

The first was a product sold as permanent hydroquinone, and is in fairly large crystals; very bright and lemon coloured. Under the microscope it showed magnificent prismatic crystals, well-defined and perfectly regular all through the slide. The prisms showed plainly a well-marked longitudinal striation.

The second sample was given to me as an entirely new preparation of hydroquinone. It is snow white, and shows the same crystalline form under the microscope as the previous sample, the longitudinal striation being also visible. The crystals, however, are very much broken up, and the sample seems to denote that very rapid crystallisation, and perhaps mechanical separation from the mother liquor, have been resorted to in its preparation.

I had the curiosity, also, to examine a sample of hydroquinone, bought when this chemical was much more expensive than it is now. This was also quite white, and exactly similar in appearance to the one just described, only very much better crystallised. Having now described the physical appearance of the two samples, I will revert to the results afforded by oxidation by nitric acid. The white sample gave remarkably constant results. The oxalic acid obtained titrated by permanganate seemed to show that one molecule of hydroquinone only yields one molecule of oxalic acid. I shall revert to this later on. The yellow sample, designated as "permanent hydroquinone," on the contrary, yielded figures differing so much that it did not seem possible to place any reliance on them.

I then proceeded to make an elementary analysis of both samples, and I must state that this compound requires a good deal of care if good results are to be obtained by burning it in copper oxide. A high temperature is requisite, and even then there is a tendency to molecular deposition of carbon. I resorted in each case to a stream of pure oxygen through the combustion tube, after the process seemed complete in the ordinary way. The results were as follows:—

	Permanent Hydroquinone.	White Hydroquinone.
Carbon.....	47.755	57.300
Hydrogen	6.745	6.196

The composition of hydroquinone, calculated from its formula, would be—

C ⁸ H ⁶ O ²	Carbon.....	65.454
	Hydrogen	5.454
	Oxygen	29.092
		100.000

It will be noticed at once that the results of both analyses differ considerably from the actual composition. However, the amount of hydrogen shown by the analysis is greater than what it should be, and this excess may be due to water of crystallisation.

Admitting this, and calculating the amount of hydrogen required for the quantity of carbon found, the two analyses show as follows, the oxygen in each case being determined by difference:—

	Permanent Hydroquinone.	White Hydroquinone.
Carbon	47.755	57.300
Hydrogen	3.716	4.770
Oxygen	21.259	25.095
Water.....	27.270	12.835
	100.000	100.000

By calculating from these figures the composition of the samples, after abstracting the water, it will be seen that the hypothesis of the presence of water of crystallisation is correct, the figures being in close agreement with the theoretical ones.

	Permanent Hydroquinone.	White Hydroquinone.	C ⁸ H ⁶ O ² .
Carbon	65.592	65.596	65.454
Hydrogen	5.140	5.481	5.454
Oxygen	29.268	28.923	29.092
	100.000	100.000	100.000

The two samples would therefore consist of—

	Permanent Hydroquinone.	White Hydroquinone.
Hydroquinone	72.730	87.165
Water	27.270	12.835
	100.000	100.000

The white sample therefore would appear to be the better of the two.

I will now refer again to the transformation of the white sample into oxalic acid. One gramme of this, oxidised three times by nitric acid, yielded by titration .600 of a gramme of oxalic acid. Theoretically, one gramme ought to give .673, if only one molecule of oxalic acid is produced, the remainder of the hydroquinone being transformed into compounds which have no effect on the permanganate solution. The discrepancy in the yield of oxalic acid would amount to 11.7 per cent. of water in the sample. The composition would then correspond to—

	Sample.	C ⁸ H ⁶ O ² .
Carbon	64.600	65.454
Hydrogen	5.434	5.454
Oxygen	29.966	29.091
	100.000	100.000

Of latter years great importance has been given to the determination of the melting point of organic compounds. Schorlemmer gives 165° centigrade as the melting point of hydroquinone. The two samples afforded the following results:—

	Permanent Hydroquinone.	White Hydroquinone.
Melting point	172.5° C.	165.25° C.

A member of the Club having inquired whether the statement that the permanent hydroquinone contains sulphite of sodium is correct, I tested the sample both for sulphur and for fixed alkali. The latter is absent, as the sample burns without leaving any residue. I found one quarter per cent. of sulphur, and no trace of sulphurous acid, so that the sulphur must be due to sulphuric acid. The quantity being very small, sulphuric acid may be a simple impurity.

ADOLPHE M. LEVY, C.E.

ART IN RELATION TO PHOTOGRAPHY.

[A Communication to the Photographic Club.]

ART is, without doubt, a happy theme to dwell upon, but many before to-night have made shipwreck of it and themselves ridiculous, and I have a sort of presentiment that before reaching the end of my short paper I shall find myself rowing pretty much in the same boat. To the oft-recurring and still vexed question as to what really constitutes art, I do not intend to make anything more than a passing allusion, for I take it that he indeed would be a bold man who would dare to come forward with an avowal that he was prepared to offer a comprehensive and satisfactory explanation of the problem. I think myself quite safe, however, in hazarding the assertion that never before in the world's history has the faculty of art been developed to such an extent, or such extensive demands made upon its resources, as at the present moment; and I will even venture a step further—this is ticklish ground I know—and say that no more powerful auxiliary has been or is now operating in the development of this result than photography. Man is, by universal consent, a religious animal, and I maintain that he is also an art animal—by that I mean that he is a being constitutionally endowed and inherently imbued with art faculties, robbed of these he would at once descend to the lowest level of the brute creation. Art and civilisation are twin sisters, inseparable and incomprehensible, springing into existence simultaneously, and at the moment when our first parents committed their first sin art played the leading character of that mystic programme, and the first creation of genius was the result; and at what a priceless value would that relic of ancient art, that historical apron of fig leaves, be held if it could only be found and identified! and who knows but what even yet some enterprising antiquarian, who would not think of allowing such a trifling thing as time to thwart his purpose, may discover it hid away in a lumber room belonging to the antediluvian ages, and bring it before the admiring gaze of the sometimes too credulous worshippers of ancient art and consecrated relics of antiquity.

It may be fairly argued that the age we live in is essentially a scientific one, that, however, affords no reason for supposing that the art instincts of man are blighted and impaired; on the contrary, there is abundant evidence to prove that they are not only in existence, but in active exercise. Art has

independent rights of her own; she is, I was going to say, her own creator, and I don't know that I should be very far wrong if I did; she is her own nurse, her own teacher and demonstrator, and she even feeds and flourishes upon her own creations. Now I really don't know what else there is you could say so much for. The universality of art is an established fact. It is a somewhat significant circumstance, and it frequently happens that the very productions which are regarded by some as crowning efforts of genius are looked upon by others with feelings akin to pity as being the emanations of a disturbed balance of intellect, or what is even more damning, denounced as fraudulent impositions to catch the nifty; pity 'tis possible to make art subservient to such artfulness. There seems to be a desire on the part of some who take an active interest in photography to circumscribe its art capabilities, to hedge it in as it were, within the narrowest possible limits, to fix by figures and measurements what shall and what shall not be ascribed to art. This, I think, is greatly to be deplored—why? than that it would be no more absurd to attempt to give us the number of square miles contained in space, or a method by which to calculate how many years go to make up eternity. The universality of art prohibits entirely any such system of treatment, and precludes the possibility of its being contained within any limits which man can prescribe. Where, then, shall art be found? Let me tell you. Not only in the great centres of civilisation, where its trophies are congregated together; not only at the seats of learning, where the highest order of intelligence is naturally looked for; it may also be found in yon almost deserted old drifftway, actuated by its genial and occult influence that poor little peasant boy, who in his ignorance never perhaps heard the name of art, and has no idea of its existence. Regard him for a moment with his rusty, old billycock hat and red woollen comforter twisted carelessly round his neck. He is breathing, although unconsciously, the very atmosphere of art, whilst surrounded with its choicest creations. See! he goes to the hedge-row and provides himself with a stick which somehow he has taken a fancy to, and now—

"He perches himself on the top of a gate,
And whilst murmuring a rustic lay,
He applies his old knife to that hickory stick,
And he whittles and whittles away."

And what is the result? Why, he has produced, in a humble form I admit, a veritable work of art; he has carved some original devices in the soft bark of that stick which may possibly become historical, and be handed down as an heirloom in his family. Ignorant of the fact himself, his art instincts have been at work, oozing out at his very finger ends. This is no unfair stretch of the imagination; it is a picture true to the life. From such and similar haunts have come the brightest satellites that ever graced the firmament of art. Although art is an innate quality of human nature, capable of further development, it does not necessarily follow that it can be brought to a high standing of excellence in all its possessors, neither is it essential that one should be able to produce results in any of its branches to prove himself a repository of art instincts; he may have true feelings of art, yet lack altogether the mechanical ability to put them into tangible shape or form. One may have his very soul aflame with poetic fire, and yet be utterly unable to give it expression.

(To be continued.)

WM. CONN.

LORD RAYLEIGH ON EXPERIMENTAL OPTICS

II.

Last Saturday, at the Royal Institution, Lord Rayleigh delivered the second of his lectures upon the above subject, and said that Herschel in his spectrum experiments worked with sunlight, and that Professor Tyndall in his researches worked with the electric light, which is richer in the heating and ultra-violet rays. Perhaps there is not so very much difference in these two kinds of light, but sunlight has to pass through our atmosphere and perhaps through other media before it reaches our eyes. The more refrangible rays of the spectrum have little heating power, but they have an influence on certain photographic preparations, and to these rays the phenomena of fluorescence are due. These phenomena were first explained by Professor Stokes, if not first seen by him. To exhibit them in lecture experiments a very bright spectrum is desirable; Lord Rayleigh obtained this by placing the slit nearer to the light of the arc lamp than usual, and by employing a better lens than usual; he then showed how paper painted with sulphate of quinine became self-luminous in the invisible part of the spectrum beyond the violet, also that a glass trough filled with solution of sulphate of quinine and placed in front of the electric lamp cut off all the rays of the spectrum which produced the fluorescent effect just mentioned. Herschel found that a solution of sulphate of quinine placed in sunlight emitted a bluish light near the surface of the liquid; he also found that light passed through one trough of the solution could not afterwards excite the luminosity in a second trough of the solution; he called it "epipolised light." At this stage of the matter Stokes took it up, and explained that it was the conversion of invisible into visible radiations; he entitled his original paper on the subject, *A Change in the Refrangibility of Light*. Stokes found an immense number of substances to be capable of producing this effect, and that they gave a great variety of appearances; he

also found that the light produced was less refrangible than that to which it owed its origin. He found that ordinary glass is by no means entirely transparent to these ultra-violet radiations, and that some of the most refrangible it cuts off entirely; he found quartz to be much more transparent than glass to these rays; he also employed reflexion from metals in his experiments, and discovered that the real spectrum is enormously longer than that transmitted by glass.

The phenomena of fluorescence can be exhibited by means of resucine; the pure substance need not be used, for it suffices to take some pump water, and merely to stir in it some pieces of the bark of the horse chestnut; such an infusion is quite good enough for the optical purpose. Leaf green, or chlorophyll, extracted by alcohol from the green leaves of plants forms a dichroic solution; in small thicknesses it looks green, and in large ones red; it also exhibits a remarkable blood-red fluorescence. Fluorescence may be distinguished from dichroic effects by the fact that the light in the former case shines in all directions, and is seen when the liquid is looked at sideways. A comparatively new coal-tar dye, uranine, gives a beautiful green fluorescence. Lord Rayleigh illustrated this by dropping a few grains of uranine into a glass trough filled with water, through which a concentrated beam from the electric lamp was passed; an exceedingly beautiful green fluorescent effect resulted.

Becquerel, said the lecturer, investigated phosphorescence, which is a kind of exaggerated fluorescence; that is to say, the luminous effect does not cease when the original cause is cut off; he also invented a clever instrument, the phosphoscope, whereby he could measure short durations of phosphorescence in a substance; he could measure, in fact, from $\frac{1}{100}$ to $\frac{1}{1000}$ of a second.

The speaker next dealt with the velocity of light, and told how it was first discovered by Römer, a Danish astronomer, by means of the eclipses of Jupiter's moons: these eclipses seem to occur later than their proper time when Jupiter is on the opposite side of the earth's orbit; in fact, light takes sixteen minutes thirty six seconds to traverse the diameter of the earth's orbit, consequently light is about eight minutes coming from the sun to the earth. He then explained how Foucault and Fizeau measured the velocity by instrumental means. Thus, he said, light is not instantaneous. Laplace proved by calculation that gravitation, if not absolutely instantaneous, is enormously greater in speed than light, yet, said the speaker, gravitation probably has a velocity. Within the last ten years two American observers have made some splendid experiments to determine the velocity of light.

Michelson, 1879.....	299 910 kils. per sec.
" 1882.....	299 853 " "
Newcomb, 1882.....	299 860 " "
Cornu (Lisings), 1878.....	299 990 " "

He had added the latter determination as one of the best of the older ones. He considered the skill of Messrs. Michelson and Newcomb to be remarkable, and that if Europe does not look out, it will soon be eclipsed by American experimentalists. He then proceeded to describe the nature of waves of light, their lengths, amplitudes, and times of vibration.

Our Editorial Table.

A NEW PRINCIPLE IN HELIOCHROMY.

By FREDERIC E. IVEY, Philadelphia.

MR. IVEY is well known as being one of those to whom photography is indebted for its power of reproducing colours in their adequate gradations of light and shade. The work before us is not devoted to isochromatic or orthochromatic photography, but to *heliography*, or the production of a photograph in the colours of nature. The idea favoured is one based on the suggestion originally made in our columns by Henry Collen, that three negatives be taken each by the action of red, yellow, and of blue light, and transparent colour prints be made by printing from each pair of these negatives in combination, afterwards superimposed on a white surface. We shall afterwards take occasion to speak at greater length concerning Mr. Ivey's valuable researches.

DICTIONARY OF PHOTOGRAPHY.

By E. J. WALL.

London: Hazell, Watson, and Viney, Limited.

It not being the first time that a *Dictionary of Photography* has been noticed by us in these pages, we may be permitted to hope that Mr. Wall (or his publishers) has "squared it" with the proprietors of the copyright (as regards title) of the original *Dictionary* which is still in force, and to the existence of which work a few words of acknowledgement would have been graceful, for it was edited or compiled by a man (Thomas Sutton) who was a giant, although perhaps unknown, even by name, to many of the photographers of 1880. In looking over this the third volume bearing the above name which is now on our shelves, we discover many differences which notably arise from the advance made between those days and the present time.

In this dictionary Mr. Wall shows that he has been an assiduous student of contemporaneous literature, and has noted much that is excellent; but in optical matters the first page to which we referred showed that he had not quite grasped the meaning of any existing writer on the subject, owing, presumably, to his not having made an intimate practical acquaintance himself with this branch. As an example: if one thing is better known to the users of lenses or has been more insisted on by opticians, it is that one main function of the diaphragm or stop is to accentuate the definition of the oblique pencils of light, the axial rays in any lens corrected for photography being almost invariably able to take care of themselves; yet here we find the employment of diaphragms recorded thus: "They are used to prevent the transmission of any but those rays which are parallel to the axis of the lens." It goes without saying that, if such were the case, no covering power would exist in any lens whatever when a diaphragm was used. We do not know what was in the author's mind when he penned such a sentence, but we advise him for his own sake to mark it for being deleted in any subsequent edition of the work, should such be called for. We feel well assured that he desires his little volume to be ultimately reliable.

There are other shortcomings, such as attributing the flare spot to the Iria diaphragm, &c., which a greater experience with practical photography will soon enable the compiler to rectify; but with such exceptions the *Dictionary* is calculated to be useful to many.

The compiler says in his preface, "I shall feel grateful if those finding errors in calculations or formulæ will communicate with me through the publishers, in order that in subsequent editions corrections may be made." The book, as a whole, is one which will be useful and suggestive to the inexperienced photographer, for whom it is mainly intended.

SOUTH AFRICA AND HOW TO REACH IT.

"To reach it" of course by the "Castle" line is at once understood when we say that the work above named (written by E. P. Mathers, F.R.G.S.) is sent to us by Donald Currie & Co., the managers of the "Castle" line of ships trading between London and South Africa.

There are numerous photographers in this country who are now seeking for "fresh fields and pastures new" in which to develop their industrial proclivities. This work does not afford any information as to their prospects in that peculiar field with which this JOURNAL is so intimately associated; but if any photographer goes to that country and can resist the temptations of the diamond and gold fields of the locality, we doubt not that, roughing it for a time, he will be eventually be enabled to sing of that *otium cum dignitate* to which so many aspire.

FLEMING'S EXPLOSIVE GAS TESTER.

A DESCRIPTION of this instrument was given on page 100 of our number for February 15. Since that time we have received the instrument itself from Mr. J. H. Steward, its maker. Its construction is shown in the above cut. To test the suspected gas the reservoir is connected with the inlet pipe on the left, the vessel having been first filled with water. When the oxygen issues from the burner its purity is ascertained by its behaviour when made to play against a piece of smouldering brown paper, as described by Mr. Baker in the article on the page above referred to.

LANTERN SETS AND LECTURES APPERTAINING TO AMERICA.

By F. York & Son, 87, Lancaster-road, W.

It is now very easy to go abroad and see the world without stirring from one's fireside, and no one has contributed more to this state of

felicitous travelling than the firm—especially its senior member and founder—before named. Before us are a series of views, most of them taken by Mr. F. York on the occasion of a recent visit to the United States of America, printed as lantern transparencies, for which purpose the negatives were specially taken. With these we have also suitable lecturettes compiled to afford a brief explanation of each subject. It is problematical whether even any resident in New York, who can "blaze away" whenever it suits his ideas to do so, has a larger or better selected set of views of that city than those taken by Mr. York during a brief stay in the Empire City; and so with other localities in the New World, from Maine to California. The subjects are selected with a view to showing on the screen with effect, the quality of the slides being unexceptionable. In the lecturettes the information given is accurate, ample, and telling.

RECENT PATENTS.

PATENT COMPLETED.

A PROCESS OF PHOTOGRAPHING IN COLOURS.

No. 4537. JEAN BAPTISTE GERMEIL BONNAUD, 39, Stroud Green-road, Finsbury Park, Middlesex.—*March 24, 1888.*

By this invention, which is simple, I am enabled to produce a painting from photographs which it is next to impossible to distinguish from an ordinary painting done by hand in the usual way.

According to this invention I proceed as follows. Having obtained positive and negative transparent proofs of the picture to be coloured, I take a solution of—

Distilled water	200 cubic centimetres.
Solid glucose	40 grammes.
Chemical gum	24 "
Bichromate of potash (very pure)	24 "
Liquid ammonia (pure) 6 drops specific gravity 0.880.	

Instead of the glucose other similar organic matter may be used, such as honey, sugar, treacle, &c.

The solution prepared as above is carefully filtered and spread on a sheet of well-cleaned glass or other substance non-porous, and having a polished surface, which is then slightly heated in any suitable apparatus until it is no longer sticky or tacky, in fact, until the finger may be passed across it without feeling a stickiness; it is then exposed to the action of light under the photographic transparent positive, and when the edges of the glass (which should exceed the size of the picture by about half an inch) have become dark brown from the original yellow colour the picture is ready to receive the colours, as hereafter described. The glass is then taken from the printing frame in which it was placed with the positive proof for exposure to the light, as above described, and then the following series of novel and curious transformations commence.

Having selected the colours which are required in the picture according to the requirements of the picture, that is to say, those tints which are specially applicable to the subject of the picture, as for instance, in the case of a portrait of a negro I begin with dark brown or brown-black tints, whereas for the portrait of a white man I begin with a pinky grey colour according to the depth of colour required; again, if it is desired to copy the picture of an old master, it is necessary to begin with darker tints than in copying a more modern picture, all of which the operator will soon find out by practice.

The necessary colours—which should be vegetable colours in powder—are prepared in dishes, and the dusting on is effected with a large-sized brush made of soft, fine hair, commencing with the dark shades and following with the half tints; the operation of dusting on the colours should be performed as rapidly as possible, the glass (which has now the picture upon it, but without any groundwork, and which hereafter I call the picture) is then again dried, but with less heat than before (in warm, dry climates this second drying is not necessary), and the picture on the glass is again exposed to the light, but this time under the negative photographic proof, which must of course be reversed

and placed on the glass so that the subject may correspond. This is what is conveyed by the provisional specification, where it is stated that a proof of the negative is laid over the proof of the positive.

The picture obtained by the first dusting protects the shades, and the reverse of the shades so obtained from the exposure under the positive is obtained from the negative, and by a second dusting after this latter exposure the different degrees of tints are obtained necessary to complete the picture—this is done by dusting on the more light colours representing the lighter shades in the picture, such, for instance, as flesh colour. The juxtaposition must be absolutely correct if the negative and positive are obtained from one another.

When the picture has undergone the two exposures aforesaid, I pour on the picture a mixture composed of boiled linseed oil and varnish dissolved in ten times their weight of spirits of turpentine, which is allowed to evaporate; any details, such, for instance, as a gold chain in a portrait which may be wanting must now be painted in by hand from oil colour in tubes as is usual. The picture, thus finished, is removed from the glass by means of a collodion composed exactly as follows:—

Guncotton.....	2 grammes.
Alcohol at 62°.....	40 cubic centimetres.
Ether at 40°.....	60 " "

This collodion is poured on and is then left for some minutes to evaporate, and then I proceed as follows in order to transfer the film with the picture from the glass to the canvas, wood, or other desired material. I steep the glass carrying the picture in water to get rid of the organic matters and the chrome salts, and when these substances are completely dissolved I steep (for a minute at the most) the glass and picture in another bath which will subsequently destroy the collodion film; this bath is composed as follows:—

Water.....	1 litre.
Common soap.....	20 grammes.
Chloride of lime.....	20 " "

This solution I prepare hot and use cold, and for the purpose of removing any particles of chloride of lime I carefully filter same through flannel before using; I then wash in fresh water the glass carrying the picture, and the film with the picture on it is then transferred on to canvas, wood, or other material. This is done by placing the material on to which the picture is desired to be transferred in a bath of water and by steeping the glass with the film (carrying the picture thereon) downwards; the film will become detached from the glass, and sinking through the water on to the canvas, wood, or other material, will adhere to it, and the glass is taken out of the water when the film has become detached from it and sinks.

Should the picture be required on wood or a material of less specific gravity than water or on a flexible material such as canvas (which should be stretched on a frame), this material must be weighted so as to sink in or lie at the bottom of the bath.

I can obtain pictures by the use of a positive proof only, and painting the same on the provisional support in the manner above described after the oiling and dusting, which is quicker and more simple, but the results are less vigorous and not so true.

I would also remark that when I wish to imitate an oil painting I first paint the material, on to which the picture is required, all over with white paint so that when the picture is transferred thereon it shall show the brush marks as in an ordinary hand painting done in oil.

When I wish to imitate water-colour paintings, after the two exposures and dustings hereinbefore described, I dispense with the linseed oil and varnish and oil colours and transfer the picture immediately after the exposures and dustings direct on to the desired material by the aid of the collodion film, as above described.

After the picture is finished it is varnished in the usual way if to represent an oil painting.

Having now particularly described and ascertained the nature of my said invention, and in what manner the same is to be performed, I declare that what I claim is:—1. The alternate use of the positive and negative proofs to produce a complete painting with the aid of light, substantially as described. 2. The use in some cases of a positive only and painting on the same provisional support, substantially as described. 3. The process for imitating an oil painting, substantially as described. 4. Removing at one operation, and transferring the complete picture to canvas, wood, or other material prepared for the purpose, substantially as described. 5. The process hereinbefore described for the production of paintings.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

On Thursday night, last week, at the ordinary weekly meeting of the above Association, held at the Masons Hall Tavern, City, London, Mr. A. Hadlon presided.

Mr. J. J. Briginshaw exhibited one of Zaehndorf's self-binding mounts issued by the Eastman Company.

A question in the box was:—"What is the cause and cure of the enclosed failure in enamelling?"

Mr. WILLIAM ENGLAND said that the gelatine did not adhere to the collodion.

Mr. A. COWAN thought that the gelatine solution had not been strong enough, and that the print and glass had not been brought together beneath the liquid. Enamelling was not conducive to the permanency of the prints.

Mr. W. H. PHRESTWICH said that some kept well, but, as a rule, enamelled prints faded more rapidly than others.

Mr. F. P. CEMBRANO stated that he had just been photographing in Spain; some of the subjects had been very difficult, such as arches with brightly illuminated objects beyond; he had had to stop down the lenses to get detail, and to use backed plates thickly coated; he had to develop nearly every negative with the brush, and to take from twenty to thirty minutes over the work. He met a German photographer there, who said that he had been photographing in France without much hindrance until he went near the frontiers, where they would not even let him take pictures of the insides of the cathedrals. Four good negatives a day were all he (Mr. Cembrano) could get over difficult subjects; he wished that he had had one of the class of lenses with him that covered more than they were advertised to cover, as it would have enabled him to make better use of the rising front of the camera.

Mr. W. H. HARRISON asked if life were safe in certain districts in Spain remote from towns, also whether Madrid were not livelier than Paris, and what was the quality of Spanish photographic work.

Mr. CEMBRANO replied that life was as safe in Spain as elsewhere. The quality of what photographic work he had seen in Spain was "very average," but neither London nor Paris could beat Madrid in photographers' show cases; they were of a gorgeous description, well got up to attract the public. The Madrid people are lively enough to go to bed at about three in the morning and get up at three in the afternoon; the amusements are plentiful and cheap; a stall at the theatre costs about a shilling an hour. One of the five Captain-Generals of Spain died while he was there and had a great state funeral; in the procession were ministers and officials, and from ten thousand to twelve thousand soldiers. He took some views of the funeral and would probably exhibit them to the Association at a future time. The amateur element is little developed in Spain. The photographic dealers' shops are as well supplied as any in London, but the prices are enormous, sometimes four or five times higher than in London. He could not get English plates there, which surprised him, as they could be sent there by steamer for a mere trifle; he supposed there was some import duty. In one place he found some English half-plates at fourteen francs a dozen, and some French ones at five francs. Sometimes he was supposed to be an American, sometimes an Englishman; occasionally he was recognised as a Spaniard, and a Spaniard he was. On the Spanish railways only thirty kilogrammes of luggage are allowed free, and the carriage of anything over is enormously expensive; he had but three or four pounds' weight over, yet occasionally had to pay as much as ten shillings excess. The railway travelling in Spain is good, but the lines are single ones only; the first-class carriages are well warmed.

Mr. ENGLAND exhibited some flash light pictures, and took two of the assembled meeting by means of three flash lamps fired off at once.

CAMERA CLUB.

On Thursday, February 28, Rev. J. PERKINS, M.A., read a paper on *Lenses*. Dr. G. Lindsay Johnson was in the chair.

The lecturer treated of depth of focus, the cause of flare spot, the relative rapidity of different forms of lenses, and other points of interest, giving mathematical formulae, and explaining the subject by diagrams, negatives, prints, and various forms of lenses, some of which were kindly lent for the occasion by Messrs. Hinton & Co.

A prolonged discussion followed, Mr. Taylor, of Leicester, and Mr. W. E. Debenham adding some remarks upon the subjects treated by the lecturer. Others who spoke were Messrs. Elder, Lionel Clark, Davison, Ferrero, and the Chairman.

On Thursday, March 14, a lantern exhibition will be given at the Club. Meeting at eight p.m.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

At the meeting of this Club on Monday evening, the 25th ultimo, Mr. H. Beckett read a paper on *Posing and Lighting*.

In introducing the subject, Mr. BECKETT said:—

When posing and lighting are finished and well done the artistic portion of photography is virtually at an end, the rest is merely chemical and mechanical. What I more particularly intend doing this evening is to give you some idea of things to be avoided, leaving the rest to your own individual tastes.

Having described his studio as being a portable erection of wood and glass twenty feet long, by ten feet wide, by nine feet high, and the curtaining of it, he continued:

To be a good operator it requires a quick, artistic eye, that is to say, one that can at a moment's glance see which is the most pleasing style to give each sitter; and I would caution you against having a fixed set of poses into which to place your subjects indiscriminately. It is, to a certain extent, a gift, that of being able to pose. With regard to *eigrette heads*, the first point to be considered is, which is the better side of the face? (for it is, I think, generally acknowledged that nearly every face has a better side). In nine cases out of ten you will find the left side takes best, because on that side the features are, as a rule, more even; the nose, for instance, almost always inclines slightly to the left. Some writers go so far as to say that the eyes are not level, and I am inclined to believe this to be (with few exceptions) the case. Always be most particular to have the shoulders level. I think nothing looks worse than one shoulder appearing lower than the other, especially when the body faces the camera. It is advisable to turn the head in a different direction to the body, as that gives life to the picture—keeping in mind, of course, the fact that this, carried too far, gives the

after the appearance of having a stiff neck (a very objectionable feature in a picture). A great deal might be said about poisoning the head, but time forbids, and I must therefore leave it, as I said before, to the good taste of the operator. Never allow the camera to be tilted too much, looking down upon your sitter, as it were, or vice versa. Those of you who use tripods must, if possible, use a high chair, so as to keep the lens as near on a level with the head as possible. When looking at the sitter always place your eye on a level with the lens, not forgetting that looking down from a height gives a different view than that which your lens lower down portrays.

Mr. Beckett then explained the necessary lighting, with a sketch of the studio and curtains, showing how to obtain the required light, namely, one that "brings out the features in bold relief;" that, as he described, being the object of lighting. He continued:

In half and full length portraits always, where possible, allow the sitter to arrange himself or herself as much as is practicable, just making the necessary alterations and improvements afterwards.

He then answered numerous questions, and showed some exceptionally fine specimens of Rembrandt's lighting for which he explained.

Then followed a short discussion on drawing-room and outdoor portraiture.

Mr. F. L. FRIER, in proposing a vote of thanks to Mr. Beckett for his paper, hoped that a few observations from an art student would not be unacceptable. He could not help feeling that the qualities of the average photograph, after all the strictly chemical difficulties had been successfully overcome, were very far removed from those exhibited in the works of the great painters of the past and present. No doubt the absence of the distinct charm of colour went far to account for the difference, but an hour spent with the masters of the Venetian and Flemish schools would convince any one that other causes contributed to render the great majority of photographers wanting in artistic interest. He was pleased to notice that Mr. Beckett had made some reference to the so-called Rembrandt effects, because there was, no doubt, much to be gained by studying the works of this great master of light and shade. A very great deal of the success of some of the favourite portrait photographers of the present day may be attributed to their acceptance of the principles illustrated by his works—as, for instance, the enlargement of a portrait of Cardinal Manning, on view at Mr. Van der Weyde's studio. Such productions show a distinct advance in the art. What has been done once may be done again, therefore let the members of this Club emulate such works as these: for, judging by the specimens we see upon the table, there is every promise that by a careful study of the means employed by great artists, we may be able, each in his own way, to produce results excellent at least in their individuality.

Next meeting, March 11.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting of this Association was held on Thursday, February 28, at the new rooms, Crescent Chambers North, 3, Lord-street,—Mr. A. W. Beer in the chair.

The PRESIDENT, before proceeding with the business of the meeting, said:—

I have a sad and distressing duty to discharge this evening. Since our last meeting I have seen laid in his last resting-place William Page Riley, one of our most promising and enthusiastic members, and I am glad that this Association, whose welfare he had so much at heart, was not unrepresented on the sad occasion. To all who knew him he endeared himself by his unselfish nature and pleasant grace. It is not necessary for me, nor would it be seemly, to do more than refer to the irreparable loss of those intimately related to him, but to us, his fellow-members in this Association, colleagues in the Council or various committees, and particularly the House Committee of these rooms, his vacant place appeals most affecting to our hearts and minds, so recently was he associated with us in the work of the Association and the preparation of these premises. The Council have passed a resolution, embodying the feelings of the members, to be forwarded to his sorrowing family, which it is not requisite for me to formally put before you, as I am fully sure it meets your wishes in the matter.

Messrs. A. E. Chevalier, H. S. Craven, R. B. Daly, A. Fraser, B. Mackerell, W. Mollath, H. Poulton, S. Parry, W. A. Roberts, H. H. Williams, and W. D. Williams were elected members of the Association.

The PRESIDENT acknowledged with thanks the receipt of a "Chairman's mallet," of a very unique and useful pattern, presented by Mr. B. J. Sayce. He then gave a hearty welcome to the members on this the first meeting in the new rooms, expressing the hope that although the opening ceremony was to a certain extent informal and homely, yet the members of the Association could now feel "at home," and trusted that the possession of Club premises would conduce, not only to the rapid increase and prosperity of the Association, but also to the comfort and pleasure of the members. A proposition was made some eight or nine years ago to secure Club premises, but this was not attainable until now, as the Council were firmly resolved not to run the Association into debt or pledge future resources. Thanks to the House Committee and to Mr. Day, their valuable and painstaking Secretary, a number of works of art have been secured for the adornment of the room from various gentlemen well known for their artistic productions.

The elections of the Council to fill vacancies were confirmed, viz., Mr. P. Lange to be Vice-President, in place of Mr. H. M. Atkins resigned; Messrs. Tyerman and C. A. Timmins to the Council, in place of Messrs. Riley and Lange. Mr. H. N. Atkins was elected an honorary member, and a vote of thanks to him for his past services was awarded.

The medals were then presented to the gentlemen who were successful in the annual price competition, as follows:—Silver medals: Messrs. T. B. Sutton, A. W. Cornish, C. W. Huson, B. Sc., and Paul Lange. Bronze medals: Messrs. D. Cunningham (2), T. K. Glazebrook, and A. W. Beer.

The President announced that the presentation prints were received, and would be ready for distribution at the rooms on and after Tuesday next.

Letters were read from the "Liverpool Gynnasium" asking for assistance in the way of photographic prints and lantern demonstrations at their Fancy Fair; from the Boston (United States) Camera Club, offering to present a series of views, entitled *Illustrated Boston*, to the Association, in trust, which was accepted with thanks.

Circulars were also distributed relating to the American Exhibition, Gaedcke's lamp, Vlac's exposure table, &c.

The Rev. T. A. Bartlett, M.A., then read a paper entitled, *A Month in Normandy and Brittany*; and Mr. Jos. Earp read a paper on *Ten Days in Holland and Belgium with a Hand Camera*, illustrated by numerous slides.

The PRESIDENT strongly recommended members to secure a copy of the *English Magazine*, in a recent number of which was an able article on Normandy and Brittany, with beautiful illustrations.

Mr. Roberts showed two stereoscopic glass slides, prepared in 1865 by the original collodio-bromide process, as published by Mr. Sayce in 1864, of rare merit and as brilliant as when first made.

Mr. Kenneth Bean exhibited a print of the *Dance of Death*.

Mr. Rogers exhibited a compact detective camera, holding six plates and set of lenses.

Messrs. Atkinson, Sharp, and Hitchmough showed a number of photographic novelties.

BATH PHOTOGRAPHIC SOCIETY.

A MEETING was held at the Royal Literary and Scientific Institution, Terrace-walks, on Wednesday, the 27th ultimo,—Mr. Austin J. King, Vice-President, in the chair.

The CHAIRMAN, in opening the proceedings, remarked that the whole world might be placed under the category of those who understood photography and those who did not, and the object of the Society was to diffuse the knowledge of photography among the latter. We have here (said the Chairman) Mr. Talbot, who, very early in the history of this young Society, came forward and promised us his assistance. This was a great help to them, for his father, who was an honour to this country, was, for all practical purposes, the inventor of photography as at present practised. Mr. Talbot had presented the Society with about fifty of the very earliest photographs. These, owing to their great historical value as well as the clear manipulation of detail, rendered them quite unique, and the Bath Photographic Society was indeed fortunate in possessing such a rare collection. The pictures would be exhibited by the Society at the Jubilee Photographic Exhibition, which opens at the Crystal Palace on the 19th proximo.

These examples, dating 1844 to 1846, were then laid upon the table for inspection previous to dispatch to London. A portrait of Fox Talbot, produced by his own process of photo-engraving slightly modified by M. Dujardin, of Paris, from a *carte-de-visite* taken by Mollat, of Edinburgh, and two original *cartes* by Mollat, were also given by Mr. C. H. Talbot, also a copy of the biographical sketch of Mr. H. Fox Talbot which appeared in the *Transactions of the Society of Biblical Archaeology* in 1879, prepared by Mr. R. Cull, F.S.A., from materials furnished by Mr. C. H. Talbot, of Lacock Abbey.

The CHAIRMAN, having thanked Mr. Talbot for his valuable presents to the Society, Mr. TALBOT said he had a few examples of the photo-engraving process left, which he would give to the members if they so desired. He explained that his father's portrait was from the best of Mollat's negatives, and Dujardin had considerably modified the photoglyptic process, but he believed that his father's later improvements made it capable of much finer results, and he thought a good many of the processes used in illustrating newspapers were modifications, more or less, of the photoglyptic process.

The CHAIRMAN said that in looking at the calotype pictures presented to the Society he was not only impressed with the delicacy of the process but the permanency, which in many cases compared favourably with much that was seen now, although above forty years had elapsed. Notwithstanding the fact that some silver prints fade quickly, these had not done so.

Mr. TALBOT gave an outline of the calotype process by which the prints were made, and said they had been selected out of a great number as being suitable for exhibition. He said he had brought thirty-two still earlier specimens, mostly dated and signed. These were handed round, and details concerning each were given. The supposed earliest example was undated, but the paper bore the water-mark of 1835. Starting with this print, the others either bore dates soon afterwards or could be fixed by events, until the last (No. 32), dated September 1, 1840, which (said Mr. Talbot) came very near to the date of the discovery of the latent image, September 20 and 21, 1840.

The CHAIRMAN thanked Mr. Talbot for his paper and for showing these specimens, which, he said, were probably the first ever taken by any photographic process in England or anywhere else. There was a great difference between those early pictures and what was done now, but they were the germ of the present processes.

Mr. TALBOT, in acknowledging thanks, said that some of the pictures he had shown were amongst those his father exhibited before the Royal Society in 1839.

Mr. FRIESE GREENE remarked that in the very early specimens of photogenic drawing it was wonderful how well they had been preserved, and it was curious to notice that every colour which from time to time has since been adopted was to be found in these experimental photographs of Fox Talbot's, made previous to 1839 with ordinary salt, potassium, iodide, and silver nitrate. In one case the colour resembled that of the Bartolozzi engravings, which tint was now very much imitated by photographers.

Some remarkable photographs of lightning flashes taken by Mr. A. H. Binden from a window of his house at Wakefield, Massachusetts, U.S.A., were, through the courtesy of a lady member, shown. No. 1 was taken July 29, 1887, looking west across the Crystal Lake. The landscape and houses (distinctly visible) were lighted by another intensely brilliant flash which took place at the same moment in the opposite quarter of the sky. Nos. 2 and 3 were taken on June 23, 1888, and were the most perfect yet produced in the camera.

Mr. J. DUTTON said his earliest photographic experience was with the calotype process; he then detailed the wax paper process, which consisted in waxing the paper, then ironing it until the wax had soaked into the body of the paper; it was next soaked in potassium iodide and dried, sensitised by floating on a thirty-grain silver bath, acidified with acetic acid, and, after an exposure of half an hour or more, the negative was made by development with a cold saturated solution of gallic acid. A number of wax paper negatives taken in the locality between 1852 and 1856 were handed round and greatly admired. He also exhibited several collodion negatives on curved glasses in which a water lens similar to that referred to by Mr. Braham in his recent

lecture was used to form the image. Prints from these semi-circular glass negatives were shown and praised.

Mr. GREENE thought circular plates might be used in astronomical photography with advantage.

The HON. SECRETARY then explained the working of "Kruger's patent book camera" which, as its name implies, resembles an ordinary book. It contains twenty-four plates in metal sheaths which are exposed in rotation, each sheath is numbered and a coloured glass window permits the number of an exposed plate to be read without opening the camera. The lens is of the new Jena glass, and, by means of a safety shutter working outside the active shutter, either a very rapid or slow exposure can be made at will.

This little camera was examined with much interest, as also was a number of specimens taken in a similar manner.

The HON. SECRETARY stated that Marion & Co. had presented to the Society for their new dark room a quantity of concentrated developers and some sample boxes of Britannia plates. The same firm had further sent to the Society, on loan, two complete sets of granatine dishes, deep and shallow, up to 16 x 14 for use in the dark room. He also announced that Mr. Dyson, of Huddersfield, had sent the Society, as a present, a sample background of opaque cloth which could be washed with soap and water when required.

Messrs. Piper & Carter presented a copy of the current *Year-book of Photography*.

Circulars and entrance forms relating to the joint societies of New York, Boston, and Philadelphia Exhibition were announced, and placed upon the table, as well as a number of photographic journals and trade catalogues.

The CHAIRMAN then reviewed the business of the evening, thanked those who had contributed matters of interest, and, after congratulating the members on the unprecedented prosperity of the Society, the proceedings terminated.

BRIGHTON PHOTOGRAPHIC SOCIETY.

A MEETING of this Society was held at 35, Vernon-terrace on the 26th ultimo, — the President (Dr. Rean) in the chair.

Messrs. Fallbrook and Tate were elected members of the Society.

It was decided that the meetings for the future be held in the Lecture Hall, New-road.

A vote of thanks was awarded the President for placing his rooms at the disposal of the Society.

Dr. REAN, having briefly replied, proceeded to deliver his opening address, which dealt with several points of interest to photographers generally, and at the close an animated discussion ensued upon several of the points raised.

It was decided that the Committee report as to the feasibility of holding a photographic exhibition in Brighton during the autumn.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE ordinary meeting of the above Society was held at the Grand Hotel, Colmore-row, — Mr. E. H. Jaques in the chair.

Messrs. J. C. Newry, Thomas Taylor, and H. S. Gent were nominated for election.

Mr. A. W. WILLS, J.P., exhibited negatives he had taken on Carbutt's films, and remarked upon their lightness and ease of manipulation. There is no difficulty in developing or in the drying; he simply reared them on end, the same as an ordinary glass plate, and they dried perfectly flat. They are made of a substance similar to "Parkesine," which was invented by one of our townsmen some few years back.

Mr. W. J. HARRISON said he thought this was certainly the best improvement in films as yet, and he imagined they could be used with advantage in "Pumphrey's film holder."

Mr. A. A. BONEHILL presented a bound copy of *Anthony's American Annual* for the library.

Mr. H. F. HALL EDWARDS gave his paper on *Photo-micrography*, giving a practical insight of the whole process, exhibiting the apparatus, &c., used, and showing by the lantern many of his own and members' micrographic slides.

The next meeting will be on March 14. — Mr. E. H. Jaques on *Holiday Trips with the Camera*.

SHEFFIELD CAMERA CLUB.

THE ordinary monthly meeting was held on Friday, March 1. Dr. Morton presided, there being a good attendance.

About one hundred slides, the sole work of members, were projected on the screen. The contributor of each set of slides gave a short description of the process he had used.

The PRESIDENT employed hydroquinone for all gelatino-bromide lantern plates, and found it the best developer. He made two stock solutions: — The first, hydroquinone, half a drachm; sulphate of soda, three drachms; water, three ounces; the second, carbonate of potash (anhydrous), one drachm and a half; water, three ounces. An ounce of potash solution was mixed with an equal part of hydroquinone in a measure, and the combined two ounces would develop at least a dozen plates. He found no necessity for citric acid or bromide if the exposure were correct, but occasionally added a little old developer (one or two days' standing, which had retarding qualities) in case of over exposure.

Mr. C. YEMANS used pyro-alkaline and meta-bisulphite. The slides shown were of an agreeable brown tint, and, being mostly landscape, proved very effective.

Mr. J. O. ARNOLD had taken his negatives on Ilford ordinary and positives, Mawson's plate, developed with ferrous oxalate; principally snow scenes.

Mr. G. K. MACHAM sent a number of slides taken on Thomas's plates; developer, hydroquinone intensified with mercury. They were reduced from half-plate and 9 x 7 negatives and exposed to magnesium ribbon light.

Mr. WINTER's slides were a set of micro-photographs by contact from negatives of objects obtained with two-inch to quarter inch objectives. He preferred ferrous oxalate developer, but had occasionally used pyrogallol.

Mr. WHITTAKER showed various subjects by contact printing, Mawson's plate, and ferrous oxalate.

Mr. HARROP contributed several slides taken by contact, iron developer; as also Messrs. Taylor and Newell.

Mr. H. J. HARDY (Hon. Secretary) used Ilford for negatives and Mawson's lantern plate with satisfactory result.

As the evening was well advanced, discussion had to be postponed. Many of the slides exhibited possessed excellent qualities and evoked much applause.

YORKSHIRE COLLEGE PHOTOGRAPHIC CLUB.

THE meeting on February 28 was devoted to a discussion on *Fine Art in Photography*. The President (Mr. C. H. Bothamley) occupied the chair.

Messrs. H. P. Robinson, F. M. Sutcliffe, and H. Tolley sent for exhibition a large number of fine examples of their work, and examples of the work of Messrs. Green, Emerson, and Sutcliffe were contributed by the President. In fact, the exhibition was quite remarkable both in size and quality.

Amongst the questions raised in the discussion was that of fuzziness *versus* definition, the general opinion being distinctly opposed to anything in the shape of decided fuzziness. The prevailing tendency to over-crowd genre pictures with unnecessary accessories was also condemned.

EDINBURGH PHOTOGRAPHIC SOCIETY.

AN ordinary meeting was held in the Professional Hall, 20, George-street, on Wednesday evening, February 6, 1889. Mr. J. M. Turnbull was called to the chair.

Four new members were elected.

The CHAIRMAN gave an historical sketch of the progress of film-photography, from its introduction to its latest development, and also indicated the general method of the manufacture of the films under discussion.

Mr. J. M'GLASHAN then proceeded to demonstrate the various processes necessitated in working with stripping films, and said: —

It is a great desideratum to photographers, especially those who have much outdoor work to do, to have a medium on which to expose their subjects which shall be at once portable and reliable and not entail too much after-labour. How far this Eastman stripping films fulfil these requirements will, I hope, be shown to you tonight by the demonstration, and the discussion which, I trust, will follow. In a new process such as this there is always a great deal to be learned by experience — what to do and what not to do — and we should not, blame the process if we fail at first and can find a remedy. Still, these films have now been on the market so long that we ought to be able to say by this time whether they are a perfect substitute for glass plates or not. I tried these films just as soon as they were in the hands of dealers, and my experience of them was most satisfactory. With the first few rolls I never had a failure. They all stripped beautifully, and are among the best negatives I have got. They were slower than plates a good deal, but that was an advantage to me in those days, as I was comparatively young at photography, and when I exposed a plate I liked to feel sure that I had got it there; I could easily afford the extra time. The consequence was that I got good results. In July last I went to West Sutherlandshire for a fortnight with two gentlemen of the Geological Survey, and, as I would have a considerable amount of tramping over rough country, I took stripping films with me as well as a few ordinary Ilford plates. We climbed a number of hills between two thousand and three thousand feet high, and as the hills there are mostly devoid of vegetation and rough in the extreme, it was no easy task. From the summit of Ben Stack there was a splendid effect which I tried to photograph. The whole country to the north was enveloped in clouds, which wore about five hundred feet underneath us, and it was beautifully clear above. The clouds began to disperse just when we were, so that it was perfectly clear to the south, and looking north it was like a sea of foam with black islands scattered here and there, formed by the peaks of the neighbouring hills peering through the clouds. Looking east and west, where the clouds were dissolving away, were wonderful effects, and I thought, "Now I will bring home something to astonish the Society!" I exposed a dozen films there and then, and, although the exposure was ample, as I thought, they turned out all under exposed, and when they were developed they would not strip, although I almost boiled them. Strangely enough, the plates exposed were nearly all over exposed, showing that the films were by no means rapid. It took me about a week to develop the six dozen of film exposures and I got scarcely a presentable picture in the lot. The quality of the negatives was further greatly marred by numerous small insensitive patches. Another advantage claimed for the films is that they completely prevent, or very greatly lessen, halation. With this I can hardly agree, as, under similar conditions, I have got fully as much halation on a paper-mounted film as on one on glass. [A couple of negatives of the same subject were here handed to the Chairman in which the halation was greater on the film negative than on that on glass.] Again, with prolonged development the developer acts to some extent through the back of the paper support, causing a grained appearance in the film after it has been stripped. Notwithstanding all these failures, I will still use stripping films when I am travelling and desire portability, because of late, having employed films which I was satisfied were new, I have been thoroughly successful.

Mr. M'Glashan having concluded, Mr. Bibbs exposed, developed, squerged to various supports, and stripped a number of "Transferotype" films, while the Secretary explained that this process was a modification of the stripping films used in the camera, and had for its object the transference of films from their original paper support to surfaces of glass, when they could be employed either as window transparencies or lantern slides; to canvas, wood, or cardboard, when they could be coloured; or to glazed porcelain ware and crockery, where the plasticity of the film permitted its adherence to curved or spherical surfaces. He further instanced the employment of this tissue on the production of a form of opal similar to that produced by the development of the gelatino-bromide film on a piece of porcelain, but at the same time he pointed out that the attachment to a grained porcelain and the removal of the paper support appeared to be attended with some difficulty.

Mr. Hadow next exhibited the Kodak detective camera, showed the mode of handling it, and explained its mechanism. This exhibit was viewed with curiosity and interest, the ingenuity of the shutter in particular being much

admired. Mr. Hallow also distributed a number of booklets on the subject among the members of the Society.

The annual dinner of the year was held in the Imperial Hotel, on February 15, when about thirty members sat down to an excellent repast. Mr. Blanc acted as chairman, and Mr. Dougall as croupier. While the loyal, patriotic, and photographic toasts were earnestly given and heartily responded to, the meeting was of a less formal and consequently of a more genial nature than is commonly the case. Several capital songs were sung, and harmony reigned supreme.

This second popular evening of the season was held in Queen-street Hall, on the 21st ultimo. One hundred and seventy-five pictures of more than average merit were thrown on the screen, some of them showing exceptional felicity of choice of subject and facility of technical skill. According to the traditional custom of the Society the necessarily somewhat monotonous succession of so many slides was at intervals broken by music. The singers on this occasion were—Miss Brown, Miss Carracher, and Miss Pearson; Messrs. Barr, Brown, and Meldrum. The proceedings were further slightly enlivened by a declaration of independence on the part of the lantern, largely due, however, to the inexperience of the Secretary, but, with the exception that the slides were passed through somewhat too rapidly, nothing occurred to mar the success of a very enjoyable evening.

PHOTOGRAPHIC SOCIETY OF PHILADELPHIA.

A MEETING of this Society was held on February 6,—the President, Mr. Frederic Graff, in the chair.

The committee on lantern slides suggested the propriety, and recommended the formation of a special series of slides illustrative of the city of Philadelphia. There must be in the possession of members of this Society negatives of places and buildings of the greatest historical interest, and a collection could easily be made (if the interest and co-operation of the members is secured) which would be of the highest value. The series would include views in the park, as well as of public and private buildings in the city, and the historical importance of such a collection need only be suggested to be appreciated.

Mr. BURROWS (a visitor) showed a form of lamp which he had advised for use with flash-light compounds. The powder was inserted on a small funnel-shaped receptacle, the bottom being connected by a rubber tube with the usual bulb. A short distance above the cup for the powder a metallic ring about three inches in diameter was suspended, the ring being wrapped with asbestos fibre. The asbestos was wet with alcohol, which, when ignited, produced a large flame, into which the powder being suddenly forced, by pressure on the bulb, was instantly consumed with a most brilliant light. Powdered magnesium thus used was entirely consumed, with practically no smoke or residue. Mr. Burrows also showed another form of the lamp, which could be used with one hand, a trigger releasing a piston which, actuated by a spring, gave the necessary puff of air to blow the powder into the flame.

Mr. LEWIS called attention to the fact that with flash lamps of similar construction to that shown by Mr. Burrows a small portion of the powder was sometimes drawn back into the mouth of the tube, which, on being ejected the next time the light was used an instant later than the main charge, was apt to make a secondary dash, which was undesirable, if not detrimental to good work. To obviate this he recommended inserting a very small piece of absorbent cotton into the bottom of the powder cup, which being blown out with the powder would prevent any getting into the tube, and would also be entirely consumed with the powder. The cotton could also be used with lamps in which the flame was blown against the powder, to hold the compound and prevent any of it being blown away and not consumed. Mr. Lewis also mentioned having been troubled by a plate frilling at the corners, which he overcame by applying blotting paper. He thus absorbed the water from the film, and by gently patting it the film was made gradually to adhere again to the glass in its original position, free from ridges or other marks.

Dr. KRED showed what was apparently an umbrella, but on removing the case and unscrewing the handle it proved to be a tripod for use with a detective or other light camera. The legs were formed of light metal tubes, each made in two sections, so that it could be extended to the full height necessary for a practical tripod. The umbrella tripod was of English make.

Mr. BULLOCK mentioned that in toning some prints on a new brand of paper he was trying, on putting them into the fixing bath, which was of usual strength, he found the albumen immediately began to dissolve and leave the paper. Thinking the bath too strong he diluted it, only to make matters worse. A teaspoonful of salt was then added to the fixing bath, which instantly stopped the trouble, and excellent prints were obtained on paper which otherwise might have been condemned.

Mr. WALLACE thought if the silvering bath was too weak it was liable to cause the trouble referred to with some paper. He recommended the use of a minute quantity of alum in the silver bath to coagulate the albumen.

SOCIETY OF AMATEUR PHOTOGRAPHERS OF NEW YORK.

At the meeting of this Society on February 12, Mr. Ernest Edwards, of the Photogravure Company, read a paper on *The Improvements in Photogravure Processes*, supplementing it with a demonstration before the audience. He presented to each person present a neat *souvenir* picture, commemorative of the occasion, representing a study of a tree, which was produced from a negative on Carbutt's celluloid film, originally taken by an amateur. He exhibited the negative, the photogravure printing plate, and printed from the latter in the press.

In reply to a question as to whether the amateur could print his own pictures in the same way, he answered that after spending fifteen dollars for the first outlay he could try it, but he did not know how much more he would have to spend before he could obtain satisfactory results.

Mr. Canfield exhibited a new oil optical lantern by Mr. J. B. Colt, which gave a well-illuminated disc. An Argand lamp inside of a true parabolic silvered reflector sent forward the rays in parallel lines, illuminating every portion of the slide equally.

A new Ross folding $6\frac{1}{2} \times 8\frac{1}{2}$ camera, loaned by Mr. Frazer and explained by Mr. DUFFIELD, had several novel features. The baseboard had a large circular aperture, on the inner side of which were metal projecting pins, in which the tripod legs fitted. Thus the weight of the tripod head and baseboard were dispensed with.

A McKellen camera and new focussing screen, sent by Miss E. Slade, was also exhibited, explained, and shown. A series of rubber cloth bands an inch wide are stretched across the face of the ground-glass frame. To use it the bands are separated, a portion going over the top of the head and the other portion under the chin.

The PRESIDENT announced the election of eight new members, and urged members to prepare exhibits for the Philadelphia Exhibition. He stated that a special ladies' meeting would be held the latter part of March, at which papers on photographic subjects would be read, and prints and lantern slides by ladies shown, and it was expected a lady would preside over the meeting. Examples of photographic fancy work would be shown. He then read a paper on *Lantern Slide Mat Cutters*, by Mr. Joseph P. Beach.

Following it, Mr. F. C. Beach exhibited specimens of the steel dies made out of dress steels bent around a wooden form. Ink sketches illustrating how the dies were formed were also shown.

A new shutter, called "The Queen Shutter," invented by Mr. Frank Burrows, and sent by Queen & Co., was also explained by Mr. BEACH. It is placed between the lenses, and operates on the open to close principle. It was very neatly made, and worked with little or no friction.

The PRESIDENT then read a paper on *Development by Separate Solutions*, by Mr. Bachrach, of Baltimore, in which some former statements were corrected; and after a motion was made and passed re-electing Mr. F. C. Beach as the representative of the Society in the American Lantern Slide Interchange for another year, the meeting adjourned.

Correspondence.

✂ Correspondents should never write on both sides of the paper.

OXYGEN CYLINDERS.

To the Editor.

SIR,—I have read the remarks of Mr. J. H. Steward about the precautions taken by Brin's Oxygen Company in refilling cylinders. It is said that the Company open the valves and empty every cylinder before refilling. I don't quite see how this can be when we are told that we can have our bottles refilled when part empty, and credited with the unused gas, also that they advise a certificate to be had of all bottles tested. I did not get any certificate with mine, nor do I know of a certainty that they have been tested. I was also assured that if an explosion did take place with a bottle it would only rip up, but the one at Dublin flew into pieces. I still think that the matter has not been thoroughly sifted, for nothing was said at the inquest as to what became of the other hydrogen bottle, which, I presume, was being used at the same time.—I am, yours, &c.,
G.

TOLLEY EXHIBITION.

To the Editor.

SIR,—Will you kindly make it known through your paper that the Tolley Exhibition at the Camera Club will close on Saturday, 16 instant?—I am, yours, &c.,
G. DAVISON, Hon. Sec.
Camera Club, Bedford-street, W.C., March 4, 1889.

ARCHER'S GAS EXPLOSIVE TESTER.

To the Editor.

SIR,—Just a word of caution to your readers about using this plan as described in last week's JOURNAL for testing the presence of explosive gas, for, in the first place, it would not be harmless if stout tubing were used; and, second, there is a danger of the tap being blown away, and possibly hitting the operator or any one should they be in its way. In the Fleming's test there is only a very thin rubber tissue to rend (such as used in the toy air ball).

I have now used the Hardwich ether tank ever since described in your JOURNAL, and have never met with any hitch whatever, and have had to resort to it on more occasions than one when I have been disappointed in the delivery of hydrogen in the compressed form, and on each of these occasions have given the greatest satisfaction, and redeemed the mistrust which is so prevalent in respect to this apparatus.

Since Brin's Company have compressed hydrogen, I have never had a cylinder, either of theirs or one sent to them, that has not been returned painted red. There are other compressors who never think of doing this, and on many occasions I have had to test, as the smell was so similar.—I am, yours, &c.,
R. R. BEARD.

RETOUCHING.

To the Editor.

SIR,—With regard to the proposal made by "J. B." in your last number that there should be a separate department at photographic exhibitions for unretouched photographs, it would be well enough, but would have no effect in determining the question whether it is necessary to

highly retouch in order to gain a prize. The only way to do that would be to let some good men send some unretouched pictures to compete with others that are retouched and mark the result. For my part, I think they would stand no chance, though, probably, pictures with only a very moderate amount of judicious working up would strike even the judges at an exhibition as being more natural and artistic than pictures where all the flesh in the face has been changed to cotton wool.—I am, yours, &c.,
JOHN MORAN.

To the Editor.

SIR,—I had often wondered why the photographs taken by an amateur friend appeared more natural about the faces, besides being better likenesses than those done at the professional studios, though perhaps not always as pretty-looking, but he tells me it is because at the shops they are all "stippled up" on the negative, so much as to make them as smooth as "elliptical billiard balls," as the Mikado would say.

I think this is very wrong, and likely to make all people with any taste disgusted, especially if it be true that it is, more frequently than not, done by persons having very little knowledge of drawing.—I am, yours, &c.,
Manchester, March 5, 1889. J. H.

NUMBERING LANTERN SLIDES.

To the Editor.

SIR,—I saw in a late JOURNAL a notice to the effect that a Boston photographer had devised some numbers for lantern slides. I am the man. I got them up myself, as I could not find anything of the sort among the stock dealers. "Illustrated Boston," of which I sent you a programme about ten days ago, was given on Wednesday evening before a very large audience, and is a success. The set for English societies will be shipped to the Liverpool Club early in March.—I am, yours, &c.,
Wm. GARRISON REED.

25, Kilby-street, Boston, U.S.A., February 15, 1889.

[Approves of this, we have slides in our possession made by F. York more than twenty years ago, which bear not only numbers, but also the titles printed on the edge of the mounts.—ED.]

AMMONIA FUMES.

To the Editor.

SIR,—On page 359 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, Mr. J. Watney Wilson, on *Ammonia Fumes*, said he would give a prescription for red and furred tongue in the JOURNAL. I would esteem it a great favour if you would inquire into it and get it inserted in the same. Trusting it will not give you much trouble.—I am, yours, &c.,
Ashford, Kent, February 26, 1889. S. W. BARNES.

[We sent the above to Mr. Watney Wilson, who favours us with the following reply.—ED.]

SIR,—In answer to Mr. Barnes's request, I send you the two following prescriptions given to me by the late Dr. B. Ridge, F.R.C.S., the author of *Glossology*; or, *The Study of the Tongue*.

When the tongue is white and furred, he recommends half a teaspoonful of bicarbonate of soda dissolved in a wineglass of water, to which add one teaspoonful of sal-volatile. Stir and drink before going to bed, or it can be taken after a meal, but not too frequently, as its action is lowering.

When the tongue is very red, and the patient is suffering from thirst and other feverish symptoms, take—

Dilute sulphuric acid	1 drachm.
Dilute phosphoric acid	2 drachms.
Tincture of Columba	2 "
Chloric ether	1 drachm.
Syrup of red poppies	3 drachms.
Water	6 ounces.

One tablespoonful in one of water three times a day. Should the tongue be scarified, three drachms of pure glycerine can be added.

I have found the above very beneficial, and take the red acid mixture when I suffer from hay fever; but as either prescription may be taken by some of your readers according to the indications of their tongues, they will have to act upon their own responsibility, and I confidently hope they will derive some benefit from these simple remedies. Should they wish to know more about themselves, they cannot do better than obtain one of the late doctor's works, viz., *Ourselves, our Food, and our Physic*, published, I think, at 1s. 6d. Apologising for taking up so much of your space.—I am, yours, &c.,
J. WATNEY WILSON.

14, St. Mary Abbotts-terrace, Kensington, W., March 4, 1889.

THE CONSTITUENTS OF AZALINE.

To the Editor.

SIR,—As the question of the constituents of "azaline" has been raised in a contemporary journal, or it has been stated by Mr. J. Spiller that he found it to be erythrosine or eosine, it may be of general interest to have other authority upon the subject.

The question is not whether I am entitled to sell any tincture of an eosine for photographic purposes, which, by-the-by, I hold that I am, but whether Dr. Vogel has supplied me with and I have sold, knowingly or not, a solution of eosine under the "pseudo name" of "azaline."

I am charged, when Mr. Spiller's and Mr. Edwards' letters are read together, as no doubt they are intended to be, to palm off a solution of eosine as being (Vogel's Br. Pat., No. 7963) the well-known azaline which is made up of quinoline red, and cyanic blue, and to obtain by this means results which could only be got by eosine, of which, according to the reading, Mr. Attout Tailfer is the "first and true inventor."

I may at once state that the sample from which this analysis is made is from the same stock solution as the one supplied Mr. Spiller.

Mr. Edwards' letter is of itself of no interest save as an illustration of how to make a loose assertion without any evidence whatsoever to support it.—I am, yours, &c.,
J. R. GOTZ.

19, Buckingham-street, Strand, London, W.C., March 5, 1889.

To MR. J. R. GOTZ.

"DEAR SIR,—I have made a careful examination of the 'azaline tincture' received on February 16th and 19th. I have investigated its physical and chemical properties, and have compared it with solutions of quinoline red, a large number of the eosine dyes, and mixtures of these with cyanine.

"I find that the said 'azaline tincture' is a solution of quinoline red in methylated alcohol. I was unable to detect in it the presence of any cyanine; but since the tincture has been made for several months, any cyanine that was put in may have decomposed. Such decomposition would be accelerated by the foreign substances present in the methylated alcohol. I was unable to obtain any evidence of the presence of any dye belonging to the eosine group.—I am, faithfully yours,
C. H. BOTHAMLEY.

"The Yorkshire College, March 1, 1889."

Exchange Column.

* No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Wanted, Dallmeyer's rapid and wide-angle half-plate rectilinear lenses in exchange for Norton's supplementary Arabian Nights, 6 vols., just issued.—Address, J. L. LEE, Victoria Works, Burnley.

Wanted, nine-and-a-half-inch Wray rapid rectilinear in exchange for nine-inch Beck autograph rapid rectilinear fitted with Barjeant's shutter; and five-inch mid-angle rectilinear by Taylor, in exchange for six-inch portable paragon by Swift.—Address, A. R. F. EVANS, 29, Roselya-hill, Hampstead, N.W.

Will exchange Humber tricycle and Selenopticon lantern, three-wick lamp, also oxy-hydrogen jet, for binocular lantern with oxyhydrogen jets.—Address, C. J. THORNTON, Photographer, Bridge-street, Walsall.

Answers to Correspondents.

* Communications relating to Advertisements and general business affairs must be addressed to "H. GREENWOOD & Co.," 2, York-street, Covent Garden, London, W.C.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

INQUIRER.—Every Friday.

NOMINATION.—About five pounds.

ENGLE.—See Lancaster's advertisement.

MODERATION (Dublin) forgot to send his name.

H. C.—The Crystal Palace Exhibition closes on April 16.

ROMAN.—You will find paste better than gum for your purpose.

F. F. N.—Call when you come to London; a personal interview is more satisfactory.

INQUIRER S.—The surface of the paper has evidently been scratched after it had been albumenised.

S. D. G.—One of the symptoms of the bichromate disease is a "breaking out" upon the hands, mostly at the back.

IGNORAMUS.—The exposure for a gelatino-chloride plate under the conditions you mention will be about five minutes.

S. A. M.—Red fog and green fog are much the same. It is one colour by reflected light and the other by transmitted light.

SCOTUS.—The presumption is that the yellow deposit is gold, but we have not tried it. For backing plates, see answer to another correspondent.

JAMES TAYLOR (Toronto, Canada).—Mansell & Co., London, or Frith, Reigate, Surrey, England, can supply views of Jerusalem and the Holy Land.

J. WATLAND asks if commercial dry plates are ever prepared with a substratum before the emulsion is applied?—Some makes are while others are not.

VICTOR.—The initials are those of a Devonshire photographer who supplies the trade only. It is presumable that the pictures being sold to artists are not copyright.

R. M. (Liverpool).—To prevent the halation you speak of, coat the back of the plate with the following composition:—Spanish brown, gum arabic, glycerine, and water.

A. Y. The spots on the negatives sent are in no way due to the manipulation, but to the emulsion with which the plates are coated—the assertion of the maker notwithstanding.

ROBIN HOOD. 1. If you paint the glass white it will obstruct the light. Ground glass will be better.—2. Yes, use blinds.—3. Any semi opaque colour will answer for the blinds.

HARTSHORN inquires why English paper is not used for photographic purposes? The reply is that English paper makers do not make a suitable article. They could do so, no doubt, but they evidently do not care to take the matter in hand.

F. K. J.—The amount of moisture caused by simply breathing on the paper would not have wrought the destruction of the negatives by itself. No doubt the gelatine image contained a considerable amount of moisture. It is always risky to print from an unvarnished negative, by any process, unless the film be perfectly dry.

L. P. (DORK) writes: "I cannot get old gelatine films off the glass; I have tried soda, but it is not sufficient. Can you recommend anything?"—Answer: Use dilute hydrochloric acid, one to fifty; this will take the glaze off earthenware, so gutta-percha or lead is preferable. Do not allow the acid to come in contact with the skin.

STRATFORD ON-AVON asks if, when at Stratford, he will be allowed to photograph Shakespeare's house both internally and externally?—We hardly think you should gain admission to photograph the interior, but the rooms are very small. The best view of the house is that obtainable from the road, from other points trees are in the way.

W. R. P. states that he has to make some stereoscopic photographs of moving objects, but has only one camera. He says: "I have heard that stereoscopic photographs can be taken with a single camera; can you tell me how to act in my case?"—Answer: Instantaneous stereoscopic photographs cannot be taken with a single camera, you must have a binocular instrument for that purpose.

BRUNNER writes: "I am a beginner in photography, and wish to make a transparency from a negative; what is the requisite time of exposure to do this?"—In reply: As you do not say anything about the lens, density of negative, or speed of the plate, we cannot be expected to give advice about the exposure. Commence with one second and increase until the requisite exposure is found.

R. J. B. writes as follows: "I have a lens which I have been told is a whole-plate triplet, but it has only two glasses. There is a place in the middle of the tube as if there had been a lens in there. The front lens is smaller than the back, and it bears a London optician's name. Can you give me any information on the subject?"—The lens is no doubt a triplet minus the centre lens. Our correspondent had better take it to the maker and get him to do the needful.

C. W. BAINSFORD writes: "The other evening I placed some negatives, of snow scenes, on a rack in the scullery to dry, and the following morning I found them covered with ice. They were then taken to a warmer apartment, where they dried. When dry they were covered with marks as if the film had been injured. Is there any remedy?"—We fear the injury is permanent, but we cannot say for certain without seeing the negatives. We have never had any of our own injured in the way indicated.

W. H. W. says: "I was recently recommended to add some alcohol to a solution of gum arabic to be used in spotting prints. On pouring a little in it caused white clots to be produced, which remained floating about in the solution. Should this be the case?"—Gum arabic is insoluble in alcohol, though a considerable quantity of the latter may be added to a solution already made in water if it be done gradually and with constant shaking. With brisk agitation the precipitate at first produced will be redissolved, unless too much spirit has been used.

S. J. writes: "After reading the articles, in one of the back volumes of the JOURNAL, on the Stannotype process, I have been trying to make the reliefs, but have utterly failed, though I have kept strictly to the formula. The only deviation has been that I have dried the tissue in a room instead of the way recommended; it took two days and more to dry. Had this anything to do with the matter? My trouble was that the unaltered gelatine, after printing, would not dissolve."—The difficulty, no doubt, is caused by the slow drying, the tissue having become totally insoluble the while. This could easily be ascertained by placing a piece in warm water before it is printed upon.

L. C. T. R. says: "Can you answer the following questions, if so you will greatly oblige!—1. I use a piece of glass tubing for a stirring rod, but find a great difficulty in keeping the inside of it clean; what can I plug it up with?—2. Can you inform me of a ready means of cutting albumenised paper in a circular and oval shape? I find a great difficulty to get a good even edge.—3. I have lately broken a large porcelain dish in which I silver paper; can it be mended and, if so, how? It is broken in two pieces only.—In reply: 1. Hermetically seal the ends of the tube by means of a blow pipe and spirit lamp.—2. Use a Robinson trimmer and shapes. The former is a small sharp-edged cutting wheel fitted in a suitable handle, and the latter a metal slab out of which has been cut the desired shape. The paper is placed on a sheet of glass and the cut out shape placed upon it, when with one sweep of the cutter the piece is cut out.—3. Mend it by mixing Price's gelatine and litharge until of the consistency of soft putty, moisten the edges with glycerine, then apply cement, and bind together. It will be ready for use in about twenty-four hours.

C. W. inquires the usual size of panel portraits.—We presume you require the size of the mounts. An ordinary panel is $13 \times 7\frac{1}{2}$, and a grand panel may be either $17 \times 10\frac{1}{2}$ or 15×12 ; you will find the former size most convenient.

PHOTOGRAPHIC CLUB.—The subject for discussion at the next meeting of this Club, March 13, 1889, will be on *Weights and Measures*. Mr. Levy will read a short paper. Mr. England will take a flash-light picture of the members.

We are sorry to learn of the death of Mr. John Williams, F.C.S., which took place on the 3rd instant. Mr. Williams was a chemist, well known in connexion with the care bestowed by his firm (Hopkin & Williams) in the preparation of rare and pure chemicals. He died at the age of sixty-five.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—Ordinary meeting, Tuesday, March 12, at eight p.m., at the Gallery, 5A, Pall Mall East, when the adjourned discussion upon the paper, *Hydroquinone as a Developing Agent*, read at the annual meeting, February 12, by J. W. Swan, M.A., F.C.S., will be resumed.

MANCHESTER AMATEUR PHOTOGRAPHIC SOCIETY.—At the next meeting, to be held on the 12th instant, Mr. J. A. Furnival will give a demonstration with his improved oxyhydrogen lantern microscope. The President will exhibit and explain a new patent detective camera, and during the evening there will be a sale by auction of photographic apparatus, the property of members.

HOLBORN CAMERA CLUB.—A Club has been formed at 100, High Holborn, under the name of the Holborn Camera Club. Amateurs or professionals are eligible for membership; the annual subscription being, for gentlemen, 5s., ladies, 2s. 6d. Discussions on technical subjects will be held every Friday from seven to eleven p.m. All interested are invited to attend. W. Rice has been elected President, and Fred. Brocas, Hon. Secretary. Full particulars can be obtained on application.

The Vienna Club of Amateur Photographers asks us to state that it will, in its corporate capacity, with its patroness, H.I. and R.H. the Archduchess Maria Theresa, at its head, take part in the exhibition being got up by the Photographischen Verein in Berlin; and that it hopes to see represented there all those English amateurs and professionals whose pictures formed such an important part of the Vienna Exhibition. All communications to be addressed to Dr. Stolze, Salzstr. 23, Charlottenburg, Berlin.

The first annual exhibition of the North London Photographic Society was held on Tuesday evening, there being a very large attendance of ladies and gentlemen. The exhibition was inaugurated by a *conversazione*, at which were recognised several members of the original North London Society (which became extinct more than twenty years ago), notable among them being Mr. D. W. Hill, its founder and treasurer, and who contributed several charming platintypes. Among other contributors to the large collection displayed on the walls were Messrs. James Martin, E. Dunmore, J. Jackson, F. G. Reader, N. P. Fox, J. Carpenter, A. C. Cossar, J. G. Hilton, and others. After the *conversazione* a lantern display of the members' work took place. This was contributed to by Messrs. J. T. Taylor, W. Bishop, A. Mackie, Oakley, Dunsterville, Clifton, Reader, Rev.—Healey, and others. The President stated that this was the first of what he hoped would be an interesting annual gathering of the members and their friends. As to the success which had attended that evening's entertainment there was but one opinion.

THE PARIS EXHIBITION.—The negotiations which have for some time past been taking place between the English railway companies and the Northern of France Railway Company are now practically completed for facilitating the journey between London and Paris by means of improved express services of trains from the French Coast. Calais will be the chief point of arrival and departure, and the new harbour works are to be completed, so as to provide the additional accommodation required by the mail and passenger steamers. As at present arranged, there will be at least four or five services of passenger steamers *via* Calais and Dover each way daily. All these services will be performed by the London and Chatham Company's fastest boats, which perform the journey on an average of sixty-five minutes. Another new steamer of the same type as the *Empress* will be ready for the service in May next. One of the new services which is to be added early in the season is the Club Special Express, which will be limited to about eighty passengers, and will leave London at four p.m., and arrive at the French capital at eleven. The railway authorities are preparing for an enormous increase in the Channel traffic.

CRYSTAL PALACE EXHIBITION.—This important spring exhibition is now nearing completion, all the space having been applied for. The exhibition of apparatus and other appliances will be exceptionally large, as almost all manufacturers and dealers will be represented. We are glad to perceive that in the Art Division a special award is to be made for the best picture in any class taken by a lady amateur. It opens on the 19th instant.

NOTICE.

We have to apologise for the non-appearance this week of several articles, in type, although we have again given eight extra columns.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1506. VOL. XXXVI.—MARCH 15, 1889.

FULMINATING COMPOUNDS.

It would appear that what we recently wrote concerning the fulminating or explosive properties of two of the numerous chemicals employed in photography has stimulated our readers into desiring to learn something more. As one reader says, "The borderland between safety and the reverse in the employment of chemicals is so very narrow that it were well other substances than silver, iodine, and ammonia be treated in like manner, so that we may know when we stand on solid ground."

Certainly there are many other fulminates than those we spoke of, and all, or mostly all, of them are made from substances in more or less daily use by photographers, although that of silver stands "proudly pre-eminent" as having caused more loss of life than any of the others, perhaps because it is more commonly employed than the others in the manufacture of amusing toys of the cracker *genre*. But we must utter a strong protest against such uses of this potent agent as one of our readers confesses to have played off against a friend, the proprietor of a well-known studio, who, seeing a black-beetle upon the floor, immediately brought down his foot upon the animal, who responded by a sharp detonation; the "beetle" being composed of a bit of wood cut into shape and blackened, and a portion of a grain of the explosive silver attached to its belly. Such *fun* may be carried too far.

Fulminating gold is much less likely to be made than that of silver, on account of the greater expense of the noble metal. This fulminate is formed by digesting chloride of gold in ammonia in excess—this gives a brownish-yellow product; also by digesting peroxide of gold in ammonia for twenty-four hours, and drying the resulting product in the open air at a temperature below 180° Fahr. It explodes with extreme violence, either by the slightest friction or by a sudden increase of temperature.

Differing in some respects from the fulminates of gold and silver, that of mercury is probably entitled to rank next to them in regard to power. Its method of preparation is analogous to that of the silver compound. One part of mercury is dissolved in twelve parts of nitric acid, and the solution is cautiously poured into eleven parts of alcohol, gentle heat being applied. When effervescence ceases, filter, wash in cold water, and dry. All the precautions recommended as being necessary when working with the silver fulminate must also be taken with the mercurial compound.

Beyond saying that copper, bismuth, platinum, zinc, antimony, and some other metals also form fulminates, we do not consider it necessary to speak of them in detail, as their preparation stands a little outside of the routine of photographic work.

In our former article we alluded to iodide of nitrogen and its terrible properties. It is disputed that this is so powerful as the chloride of nitrogen, which, by the way, we did not assert. The fact is, that we feel quite chary at instituting comparative trials of merit between compounds of such a nature, and we are quite willing to yield the point in favour of the chloride to whomsoever chooses to back it against the iodide. We know that M. Dulong (its discoverer) and Sir Humphry Davy (one of the first to investigate its properties) met with severe injuries by its agency. Fortunately it is more difficult of preparation than the iodide. One ounce of chloride of ammonium is dissolved in twelve ounces of hot water, and when the temperature has fallen to 90° Fahr., a glass bottle of chlorine is inverted over it. This is absorbed, and in fifteen to twenty minutes oil-like globules of chloride of nitrogen form on the surface and sink to the bottom, where they should be received in a leaden saucer. A minute globule no larger than a grain of mustard seed is quite large enough to experiment with. Following advice received, we placed such a portion in a platinum spoon and touched it with a tiny morsel of phosphorus, when the explosion that resulted shivered all the immediate surroundings into fragments.

When some one is found enterprising enough to investigate the photogenic properties of these extremely touchy compounds, it is probable that the discovery of a body possessing a hitherto unknown degree of sensitiveness may reward the courageous experimentalist.

BICHROMATE OF POTASH AND ITS PHYSIOLOGICAL EFFECTS.

The employment of the bichromates in photography is more extensive now than at any previous period, owing to the more general adoption of photo-mechanical processes. This, no doubt, fully accounts for the number of anxious inquiries we from time to time receive as to the injurious effect the bichromate of potash is said to have on the health of its users. At a recent meeting of the West London Photographic Society this very question was raised in connexion with carbon printing.

We have, on more than one occasion in years past, treated of the pernicious action which this salt has on some of those by whom it is employed, in cases which we had the opportunity of diagnosing, and which, in some instances, were slight, and in others severe. As the use of the chromic salts in photography is so much increasing, we shall here make some further remarks on the inconveniences that may accrue from its employment, unless due care be taken.

The injurious effect of the bichromate may be experienced

in two forms, each totally different from the other. So far as our observations go—and they are endorsed by no less an authority than Dr. B. W. Richardson, who has since given a great deal of attention to the subject—one is chiefly caused by contact of the flesh with cold concentrated solutions, when the skin is abraded; the other from continually using more dilute ones at a tolerably high temperature, such as in developing the bichromated gelatine image in warm water. With cold solutions, even when they are concentrated, no injury appears to result unless there happens to be an abrasion of the skin, when an immediate smarting sensation is experienced; sometimes this is followed quickly by inflammation, and the part becomes very painful, and eventually ulcerates. When ulceration once commences it is very difficult to arrest; frequently it does not end until it has penetrated to the bone. These sores are very slow in healing, and it is unnecessary to say they are of a very painful character.

Some years ago a solution of bichromate of potash, acidulated with sulphuric acid, was recommended for cleaning old negative glasses, but the injurious action it was found to have on the hands led to its abandonment. A similar solution has been used for batteries, and its employment has, in some instances, been attended by serious inconvenience. Bichromates are employed in one of the processes of oil refining, and here again, we are informed, the workmen often suffer from painful ulcerated sores. Therefore, in employing the salt, say in the preparation of sensitive surfaces for photo-mechanical purposes, or in sensitising carbon tissue, the greatest precaution should be taken.

Sometimes the bichromate is pulverised to facilitate its solution. When this is done the crystals should always be slightly moistened with water. This will prevent the finer particles from being disseminated as dust, which, if inhaled through the nostrils, produce a violent irritation and irresistible sneezing. We are told that powdered bichromate of potash has, before now, been used as an adulterant of snuff to increase its pungency. Dr. Richardson, in a paper he read before the Medical Society a few years back, mentioned that, in the factories where the bichromate of potash is made, some of the workmen have entirely lost the septum of the nose through the constant inhalation of the fine particles as dust.

The ill-effects above alluded to are what may be termed the immediate result of the use of the bichromate, inasmuch as they are, more or less, manifest from the first. Not so, however, with the other form of the evil—that arising from the use of warm dilute solutions—as in this case the injury does not display itself for a long time, generally several months, or may be for a year or two. When it does, however, it is of a very unpleasant nature, and it has been named by Dr. Richardson the "bichromate disease." This disease is a cutaneous one, and takes the form of a thick red rash, accompanied by violent irritation; the skin becomes destroyed, dries up, and then exfoliates in bran-like scales. In general appearance the disease closely resembles one form of pityriasis. In the more acute stages the rash is accompanied with small pustules containing matter, and, when they die away, the skin assumes a parched appearance, like that of dried leather, and then cracks on the joints, causing painful sores. Eventually this hard skin peels off in thick, horn-like scales. The disease, in any form, is an exceedingly painful one, and the irritation is at all times most intense.

Fortunately, so far as we can ascertain, the disease is quite a

local one, being limited entirely to the parts which have been in contact with the solution. It is chiefly confined to the backs of the hands, the backs of the fingers, and the wrists, or where the skin is the thinnest. It does not appear to touch the palms of the hands at all, or when the skin is thick, or to extend to other parts of the body. Unfortunately no really successful treatment is known. If, however, the use of the bichromate be discontinued—the exciting cause removed—the disease quickly disappears, nature curing herself. Experience proves that, if once the disease is contracted, although it may be cured and remain so while the contact with the bichromate is discontinued, it is always liable to make its reappearance, sometimes in a day or two, if the use of the salt be resumed.

The question has frequently been put as to whether there is any danger to the amateur, who may only use the bichromate in a small way, as when experimenting in bichromated gelatine processes, or occasionally doing a little carbon printing? Our reply is that, in our opinion, the amateur runs no risk whatever of the bichromate disease, providing ordinary care is taken, and the hands well washed immediately after work. So far as we have been able to learn, it is only after prolonged and constant working that any inconvenience is experienced.

On a future occasion we shall describe more fully the precautions to be taken, the earliest symptoms of the disease, and the best known methods of treatment.

CONFUSION IN WEIGHTS AND MEASURES *VERSUS* THE DECIMAL SYSTEM.

AN article by Mr. J. B. B. Wellington, on page 179, introduces for the first time among our British Society transactions the thin end of the wedge. It will, we suppose, have to come to it some day, and the good old system of grains, drachms, and ounces of two different degrees will have to succumb in favour of the more rational decimal system of the French—not, however, that this system is confined to the French, for it is now permeating every class of scientific society, both in the country of its nativity, in England, and in America. As we say, we will have to come to it sooner or later, and it is well to be getting prepared for the inevitable period of the popular introduction of this system. To pave the way for the advent, we purpose, at brief intervals, to give short descriptions of the decimal system, and show in what manner it compares with that so long in use in this country.

The subject may be probably divided into three different heads—fluid-measures and weights, longitudinal measurement, and thermometrical degrees.

Our fluid-measures certainly occupy an extremely anomalous position. Some years ago, in Scotland, if one asked for a pint of any liquid, the question in response would be, what kind do you mean—imperial or English? (there being a vast difference between the two); and at the present moment, in the two great countries, America and England, the pints are quite dissimilar. A fluid ounce of ether, as every one knows, represents a totally different quantity from the fluid ounce of sulphuric acid, necessitating the explanation that bulk varies. Then as to the ounce, it, like the pint, is susceptible of more than one interpretation; an ounce of silver is a different quantity from an ounce of nitrate of silver. The same with our pound, which consists sometimes of sixteen, and sometimes of twelve ounces.

In American formula, for example, we frequently meet with the explanation that the weights are troy, or avoirdupois, or in

some cases apothecary's, and when no such distinctive appellation is made, the ordinary aspirant for accuracy is left to his own resources, and guessing enters largely into the computation.

Equally when we, on this side of the Atlantic, compare the pint with that used in America, we seldom realise that it is short of our own admeasurement to the extent of four ounces. Even the hundredweight of the New World is short of that which we employ by twelve pounds. Many other anomalies might be mentioned. Verily, there is much room for reform.

In the French decimal system, Greek prefixes are used to denote the multiples of the units, and Latin prefixes the fractional parts of the units.

The Greek prefix	Deka	means	10 units.
" "	Hecto	"	100 "
" "	Kilo	"	1000 "
" "	Myria	"	10,000 "
The Latin prefix	Deci	"	$\frac{1}{10}$ of a unit.
" "	Centi	"	$\frac{1}{100}$ "
" "	Milli	"	$\frac{1}{1000}$ "

To give an illustration of this in a measure of length (the metre)—

Myriametre	=	10,000 metres.
Kilometre	=	1000 "
Hectometre	=	100 "
Dekametre	=	10 "
Metre	=	1 metre.
Decimetre	=	$\frac{1}{10}$ of a metre.
Centimetre	=	$\frac{1}{100}$ "
Millimetre	=	$\frac{1}{1000}$ "

And so on with other units—such as the gramme, with its various prefixes; and the litre, with those by which it is qualified.

DURING the existence of the mania, as it may be termed, for magnesium flash illumination, it is well to remember that there has always been a practical field of usefulness for artificial light in photographic operations, as witness the several forms of apparatus devised, and sometimes patented, for adapting such lights to portraiture. The advantages of an instantaneous light in the avoidance of drifting smoke and of any movement of the living subject during the exposure are not to be undervalued; but it would be unfortunate for the really useful character of the older kind, of what might be called pyrotechnic illumination, to be lost sight of entirely. With these thoughts in view, we may give experimentalists an opportunity of trying the older forms of artificial light by giving the most recent formula for a brilliant and actinic artificial light. A writer in the *Chemiker Zeitung* has recently given the following formula for a penetrating light, which, it is stated, is visible in clear air for a distance of a hundred kilometers:—Magnesium powder, 20 parts; barium nitrate, 30 parts; flowers of sulphur, 4 parts; beef tallow, 7 parts. The tallow is added in a melted state, and the mixture is sifted. This mass, filled in strong zinc case ten centimeters high and seven in diameter, burns for twenty seconds with a light of 20,000 candle power. Making a rough estimate, this might weigh about a pound, and as it would be one third magnesium, its cost is quickly seen. Of course, such an immensely powerful light would be needlessly great for portraiture.

Our readers will scarcely need reminding of Mr. Muybridge, who, with his marvellous pictures (taken by wet collodion, before gelatinobromide had obtained such a thorough hold upon photographers) excited such absolute enthusiasm among photographers and painters, and in the world of society, a few years ago; and they will be interested to learn that he has already commenced to lecture in this country on his favourite subject, initiating his course by appearing on Tuesday and Wednesday at the Royal Academy before a large and select audience of academicians and their friends. We observed a very great

improvement made upon his first efforts, the figures in which were mostly silhouettes; whereas now they were all fully exposed, showing detail throughout. He had arranged to give a lecture at the Royal Institution after Easter, but owing to the illness of the appointed lecturer for the 22nd instant, he has kindly promised to take his place.

Mr. DAVID P. TODD, writing from Amherst College Observatory to *Nature* last week, states, with regard to the last eclipse of the sun—particulars regarding the photographing of which have been fully given in these pages—"More photographs of the corona were taken than ever before; many of them indifferent and worthless, but an unusually large number of great excellence. The best that I have so far seen were taken with five-inch telescopes by Mr. W. H. Pickering, at Willow, and by Capt. R. S. Floyd, at Lakeport, both in California. The latter's lens was newly made by Clarke, on the Stokes-Pickering plan, convertible from optical to photographic use by reversing the crown lens."

We recently transcribed an account of the discovery of one of the most powerful reducing agents known to science, further experiments with which confirm all that has been said regarding its remarkable reducing properties. It appears that not only is the amidogen hydrate itself distinguished in this manner, but its salts also, at least so far as tried—the carbonate, nitrate, oxalate, and acetate.

We have from time to time described the experiments of M. Fonel in ascertaining the limits of depth to which light penetrated sufficiently to permit of photographic impressions being obtained in Lake Geneva. M. Asper, another Swiss naturalist, also engaged in similar operations, but did not confine his experiments to one lake only. So much interest have naturalists felt in these investigations, that a special commission was appointed by the Society of Physics and Natural History to study the subject, and have issued their report. The first-named workers changed their plates at night time, "thus neglecting the action exercised on the sensitive plate by the light which still exists in the sky, even on a moonless night, at the moment of putting in or taking out." Monckhoven's plates were used in a special contrivance for shutting off all light, other than that which really penetrated at the depth to which each plate was plunged under water. With regard to Lake Geneva, 170 metres was found to be the maximum depth in September, in dull weather, when more light penetrated than in August.

The most interesting results, perhaps, were recorded in the Mediterranean experiments, as none of a satisfactory nature had before been made, the experiments in the *Porcupine* having been given up through the failure of Mr. Siemens's apparatus to work. Plates A, B, C, D, E were exposed at depths of 280, 350, 360, 380 metres for ten minutes each, except B, which had five minutes. A and B were much impressed; C, D, and E the impression diminished very regularly with the increase in depth. On plate E the exposure was notably inferior to that given by an exposure of the same length of time in the air on a clear, moonless night. It was concluded that, in the month of March, at least 400 metres was the maximum depth to which daylight penetrated in the Mediterranean—twenty metres lower than in September.

ON THINGS IN GENERAL.

If the extremely sad explosion accident at Dublin should have no other effect, it will have taught the lesson that explosions are the result, in most cases, of carelessness on the part of some one connected with the consumption, and not the manufacture, of compressed gas, for it is evident that any one may with safety use Brin's compressed gas with the assurance that it left the premises of the latter in a perfect condition and properly described. If the storage of compressed gases were universally carried out in a uniform manner—burning gases in a red, and oxygen in a black cylinder—it would be a most excellent thing, and there could be no difficulty in making it illegal to do otherwise. (It must not be forgotten, however, that oxygen and hydrogen, or coal gas, are by no means the only compressed gases offered for

sale, and we might want all the colours of the rainbow for the purpose.) One point to be gained is the bringing home to the minds of the inexperienced the fact that there is a danger in connexion with the use of gases. Many amateur exhibitors have as much acquaintance with this as the casual oarsman who, with his friends out for a day on the river, stands up and changes places in a crank skiff with perfect nonchalance, ignorant of risk. The same in oxygen manufacture. I know of a worthy clergyman who had been a lantern exhibitor for twenty or thirty years, always made his own oxygen, and was aghast at the mere suggestion that there were possible elements of danger in the latter process. I believe the most terrible and fatal explosion that ever occurred during the latter operation was discovered long after to have been caused by the manganese oxide having been ground in the same mill that had just previously been used for grinding coal into fine powder.

We do not now hear anything of the commercial use of the oxy-hydrogen light for enlarging, though at one time it was in great repute for the purpose. At the meeting of the London and Provincial Photographic Association early last month, enlarging matters had a fair share of attention, but no reference was made to this subject. It is a matter of surprise that neither at this meeting nor at that of the Society of Arts, when discussing Mr. Beck's paper upon lenses and the use of coloured screens, was any prominence given to the practical usefulness of the plan of using a loose stained film of collodion or gelatine. I have seen negatives made with the intervention of such a screen, in which it was next to impossible to discern anything that would distinguish it from another negative taken under precisely similar circumstances, except that the screen was not used. Whatever the value of orthochromatic plates may be in the ordinary everyday work of photography, it is certain that no danger to definition need be apprehended from the use of screens—a plan infinitely to be preferred to that of tampering with the surface of a lens by coating it with coloured collodion, &c., and wherein the experimenter, too, is in effect confined to the use of a single colour if he makes a series of exposures in a reasonable time.

Another difficulty, amusing enough, but extremely real, was that propounded by Mr. A. Cowan at that Society. He wished to know what principle of measurement to adopt to make two pictures to match as companions, when one was a man with a bald head and large beard, and the other a woman with a big chignon. It would be just the same if instead of the chignon she wore a tall cap; the difficulty would be as great, and the more likely to occur at the present time than the other case. Mr. Bridge was quite right in what he said; he used no measurements, but judged of the effect. It is not every one who has conveniences to enable him to adopt Mr. Bridge's practice of throwing the two heads side by side on to a screen and judging of the effect. The plan for those, and they will be the majority without such means, will be to take one negative first to the required size, and then compare it with the image of the second, and adjust the latter till it looks all right. But there is always an unsatisfactory element in this kind of work.

Connected with the topic of enlargements is the framing of pictures, and at the North London meeting on February 19 there was an interesting discussion on the subject. The conversation arose on the question of a discolouration of the tints in a platinotype print, the Chairman—the worthy editor of the "BRITISH"—giving his opinion that the change was brought about simply through the infiltration of dust and smoke. Although, as he pointed out, a similar effect in carbon prints was some years ago shown to be caused by the action of light upon a particular kind of paper—that made from wood pulp—there can be little doubt that he correctly diagnosed the disease; and if all photographers would adopt the proper method of framing a picture when sending it out so protected, there would be a far smaller number of so-called faded pictures than there now are. Mr. Hart fully described the required method. Every one must have noticed, at one place or another, framed pictures upon the mount or the margin of which a yellowish-grey stain was to be seen in patches of circumscribed dimensions, caused by the pasting paper having given way at the spot; it can easily be imagined how the whites of the whole surface of the picture must be degraded when there is no protecting paper whatever. The plan mentioned by Mr. Clifton of sealing up an engraving by stretching it damp across the glass of the

frame, and pasting a thin margin round on to the other side of the glass might do for small pictures, but it is very probable that with a large engraving, if it did not, as would be likely, quite break the glass, by its contraction when drying, it would bring about a curving of the surface. But beyond this, it would afford so little circulation of air that the ultimate growth of mildew would be very probable.

I was sorry to read Mr. Haddon's remarks upon what I had written regarding his views upon lenses, and the action of their periphery. He complains, first, that my remarks are unjust by reason of my having separated a portion of his observation from the context, and, further, that my version was inaccurate. I take the report in this JOURNAL (p. 131) as the basis of what I am now saying. I have no desire to start a polemic with Mr. Haddon, whose practical and theoretical skill I bore willing witness to, but I have to say that his is a most unjust and baseless accusation. I gave a word-for-word quotation, and reference to a page, and if the report be inaccurate it is not my fault, and, as to the absence of context, I dealt only with a particular phase of his observations, and not the whole. I had not the slightest intention to misrepresent him, nor do I think I did in any way. I might equally, taking the last report, say he misquoted me in representing me as saying that "an annular ring on the back lens did no harm," for I wrote of the covering the anterior lens, which it is not usual to term the back lens; and, further, I certainly never used any such absurd expression as an "annular ring." This I put down to misreporting, though after all it does not touch the argument. Possibly Mr. Haddon was misreported in the first instance, in which case I hope he will withdraw any imputations upon my candour. Has Mr. Haddon tried this partial obscuration of the lens-surface upon a positive lens with a sharp margin?

FREE LANCE.

ON THE VALUATION OF HYDROQUINONE.

THE paper by Mr. Adolphe M. Levy on *The Valuation of Commercial Hydroquinone*, read before the Photographic Club and published in last week's issue, is of special interest to me, since I have been for some time experimenting with the substance in question, and have on hand at present an unfinished series of experiments in which I have been comparing its developing value with that of pyro. The communication is also of value to photographers generally, since it is perhaps the first definite examination that has been published of the actual preparations supplied for their use, though its bearing is purely chemical rather than practically photographic.

Looking at the matter from the photographic point of view, and comparing Mr. Levy's analysis and his deductions therefrom with my own experience with the various makes of hydroquinone I have tried, and they are many, I must however confess to a slight feeling of surprise; for whereas science and practice are usually found to walk hand in hand, and the purest products generally prove the best in actual use, I am in the position of having pinned my faith, after repeated and careful trial, to a preparation that receives but a dubious character from the scientific chemist. When I say a dubious character, I do not mean that permanent hydroquinone is definitely stated to be inferior to other samples, nor that it has been found deficient in quality either from want of care in preparation or from the presence of impurities, but that, *ceteris paribus*, if another sample excels it because it contains less water of crystallisation, and is consequently a purer—in the sense of being more concentrated—product.

The difference is no slight one, amounting as it does to more than double the percentage of contained water; but the most surprising circumstance to me is that even the better of the two samples examined should contain so large a proportion. I had never imagined that hydroquinone was anything but anhydrous, have never to my recollection seen mention of any modification of it in which the properly prepared crystals retained any moisture, and have certainly never in the course of my varied experiments with it had reason to suspect such a state of affairs as more than twenty-five per cent. of impurity—or, at least, of useless matter—in a product I have come to consider, if not immaculate, at least as perfect as modern chemistry can secure; while under the most favourable conditions, and with the best sample examined, the percentage is only reduced to one-half of that mentioned.

Before going further there is one point I would like to mention, in

which, for very obvious reasons, I should have liked more information in Mr. Levy's paper, namely, the particular make compared with the "permanent." For one thing, if there is a decidedly better kind than "the yellow hydroquinone," I should like to have a chance of trying it; but independently of that it would be interesting to know whether the difference in composition is due to the process of manufacture, to the method of giving the "permanence," or merely to accident; and in order to judge of these questions it would be desirable to know whether both the specimens examined were by the same maker, and if not whether the white sample was of English or German manufacture. Mr. Levy may reply that he desires to avoid any appearance of advertising any particular make, which would undoubtedly have been a proper motive had he confined himself to calling attention to the wide difference that may exist in commercial samples unspecified; but, unfortunately, by naming the permanent as one of the kinds tested, he has singled out a particular maker, and placed it in the power of his rivals one and all to point to his production and say that it has been found inferior to *all others*: for, in this instance, it is *white* hydroquinone against *yellow*, and the only representative of the latter is the particular sample mentioned by name.

I do not for a moment think that Mr. Levy has done this with the intention of depreciating the yellow sample; on the contrary, the comparison of the new make with the white is not only a natural but also a most desirable one; but by individualising the other make tested it would have placed it beyond the power of *more than one* rival to make use of the supposed superiority of the white crystals.

On the subject of the presence of so large a quantity of water, I can say nothing in the face of Mr. Levy's careful and exhaustive examination, except that it is very surprising. Since reading the article, I have made a rough experiment in order to try and find water of crystallisation, but with negative results. About one gramme of hydroquinone was introduced into a long glass tube, one end of which was connected with a small continuous blast bellows, the other being passed into a glass receiver, unstoppered; a plug of cotton wool being interposed between the bellows and the hydroquinone. The latter was brought to a state of fusion by means of a spirit lamp, and while in that condition a gentle stream of air was passed through the tube, carrying its vapourised contents into the receiver.

I had thought that if so large a proportion of water as even twelve per cent. were present, some distinct traces of aqueous vapour would have resulted from the above experiment, but, so far as I could see, there was not the faintest sign of such. The hydroquinone sublimed in dense white fumes, and settled on the sides of the receiver as a fine deposit with a tinge of purple-grey. On the inside of the tube, as the fused material was slowly driven before the flame, a deep purple condensation took place, which was remelted, vapourised, and driven into the receiver as the flame advanced. Very little discolouration beyond that mentioned occurred, and at no stage of the process could I detect any condensation of aqueous vapour. If, then, water be present, it must be in a more intimate state of combination than as a mere accidental mixture, due to imperfect drying.

Another test for water, which I commenced before this experiment was made, now promises me little better hope of success, but I mean to carry it through. A number of accurately weighed portions of the crystals, from three different samples, have been placed in partial vacuum over strong oil of vitriol. If, at the end of a week, no appreciable difference has occurred in their weight, I shall conclude that the water, if present, is somewhat more than mechanically combined, and that the formula and composition of hydroquinone as usually given require reformation, or that Mr. Levy's deductions from his elementary analysis are incorrect.

W. B. BOLTON.

(To be concluded in our next.)

ECHOES.

I Boston in the discussion on hydroquinone following the reading of Mr. T. Charters White's paper at the Camera Club, Mr. Lionel Clark mentions a peculiarity in the behaviour of paper proofs under treatment with hydroquinone that I have myself experienced and which I had set down to the fault of the paper that I have used having been in my possession a considerable time, and possibly partly decomposed.

Now, however, that an independent worker has noticed the unequal action of the developer upon paper, or rather the irregular progress of the action, I presume that the peculiarity is general with paper, and it would be interesting to attempt to trace it to its source. I observe that Mr. Clark's experience is with bromide paper and caustic potash as the alkali. I have met the same behaviour with chloride as well as bromide paper—both very old—and with both carbonate of potash and carbonate of soda. In all cases of full exposure no trace of unevenness remains in the finished print, but with under exposure some difference always remains, proportionate to the degree of under timing.

The same speaker makes what I consider an accurate observation with regard to the reason of the great popularity hydroquinone has attained in France, namely, that it there "had a much feeblener enemy to contend with," in ferrous oxalate, than in this country it has with pyro. This is quite true as regards negative work, but the matter is altogether altered when we turn to developed positives. In that department I fancy ferrous oxalate will prove a more stubborn antagonist than will pyro in the negative department. I say this in the full knowledge of what has already been done in positive work with hydroquinone, and I speak as one who personally prefers it for the purpose to ferrous oxalate. But the latter has got so strong a hold, and has come to be looked upon as so pre-eminently the paper developer, that it will be difficult to oust.

I must also heartily re-echo Mr. Lionel Clark's opinion that the millennium will be a failure if it is to depend upon an "automatic" developer. Can anything be more ridiculous than some of the "modern" requirements? Automatic developers, automatic swing-backs—another *desideratum* (?) actually mentioned in last week's and previous numbers—and similar contrivances, will some day perhaps entirely eliminate the necessity not only for mechanical exertion but also for brain exercise. Then indeed will be the millennium of one class of amateur photographers.

"Every one his own photographer for sixpence," or very similar words, once formed the external inscription on a package containing a number of the so-called "magic photographs," a mere immersion of which in water sufficed to produce a picture. Perhaps if a packet of similar papers or plates were added to each "guinea set," we should be one step nearer the modern amateurs' millennium.

Truly "there is nothing new under the sun," even in connexion with "sun painting." Mr. F. E. Ives's *New Principle in Heliography* is nearly as old as photography itself—in idea, at least. It was brought to partially practical phase by Ducos du Hauron a dozen or so years ago, but failed of complete success from inherent difficulties. Mr. Ives has at the present time better means at his disposal in orthochromatic plates for the production of the negatives, but he is no better placed for imitating the spectrum colours with artificial pigments, or in the production of pure black or pure white without being able to supply in pigment form equivalents for the "invisible" rays of the spectrum.

JENIUS.

FLASH LIGHT EXPERIENCES.

As most, if not all, of the articles on the flash light which have hitherto appeared in the JOURNAL have been either descriptions of apparatus or demonstrations given before the various societies, it has occurred to me that a detailed account of the process in ordinary practice may not be uninteresting to your readers; for after all, however successful a process may be demonstrated by an expert with every detail carefully prearranged, and every possible cause of failure anticipated and guarded against, the real commercial value of the process can only be ascertained by practical experience in the ordinary routine of business. I think, moreover, that especial interest attaches to the present "experiences," inasmuch as, notwithstanding all that has been said and written in favour of the "blow-through" method, and the use of a screen between the flash and the sitter, actual trial and comparison (in my hands at least) has shown that the best results are to be obtained by the gun cotton method and the naked light; and for the reasons following, amongst others, first, the flash, although sufficiently "instantaneous" to avoid movement, is not so sudden and startling as the "blow-through" method, and, secondly, the yellow flame of the gun cotton mellow and softens the otherwise intensely white magnesium flame, at the same time, by using the naked light, producing that sparkle and crispness which characterises the flash light portraits, and

giving them the sunny appearance to which attention has so frequently been directed.

For the sake of conciseness, and at the risk of being considered unnecessarily minute, I propose to deal with the matter under headings as follows, merely premising that it is the outcome of attendance at four fancy dress balls—two in January, 1888, and two again this year—during which I secured upwards of ninety successful negatives (in addition to others obtained in the studio):—

A large and well-lighted ante room, in close proximity to the ball room, was secured, which answered the purpose of *studio* admirably. The apparatus consisted of studio camera and stand, and Dallmeyer's 3 B lens; for background, exterior and interior on rollers were used, screwed to two eight-foot battens, and simply placed against the wall. The best results were obtained when the backgrounds were darkish in tone.

The dark room for changing the plates was made by placing a small clothes horse upside down on a table, throwing over it a dark cloth, and lighting with ruby lamp.

If ordinary plates were used, the extra rapid series did not answer so well.

The lamp was of tin and of the simplest form, consisting merely of a fourteen-inch circular disc for base, and a semi-circular reflector fourteen inches high with handle. I prefer the hand lamp, as the position, height, and angle of inclination can be more quickly varied to suit the subject.

The charge consisted of twelve grains of guncotton, opened out to about four inches, and sprinkled with twelve grains of magnesium powder, placed upon a sheet of gauze and fired, after the word of caution had been given to the sitter, by a lighted taper through a small hole in the base of lamp. During the exposure the gas was kept full on (there was abundance of it, there being no difficulty in focussing by its aid), it being found that not only was no harm done to the negative, care being taken to keep the jets out of the field of view of the lens, but it was of distinct advantage to the sitters, tempering as it did the exceeding brilliancy of the flash to the eyes, and preventing in a great measure the staring expression which is one of the difficulties of the process.

Respecting the cast shadow, where length of room permits, it is best to place the sitter five or six feet from the background; but where space is limited, as in my case, by the simple arrangement of a curtain on a moveable stand, the shadow was trapped, as it were, by being allowed to fall behind.

For reflector, a sheet thrown over a stand about six feet high, and placed within a few feet of sitter, answered every requirement.

For developer, no finer or more suitable formula has been published than that by the editor on p. 468 of the 1888 ALMANAC, with this variation, that instead of using equal quantities of the two solutions, six parts of the alkalies to two parts of pyro, with equal quantity of water, was found a better proportion; the development was slow, but the loss of time was amply repaid by the range of gradation obtained, and the bringing out of detail in the shadows; and besides, as all the negatives received the same exposure, a great saving of time was effected by developing in batches, as is my practice: the negatives required very little retouching.

In conclusion, I deprecate the statement I have seen repeatedly, that "portraits by the flash light cannot be distinguished from those taken by daylight." They are not as good, nor is it reasonable to expect them to be. At the same time, there can be no question that the introduction of the flash light has placed a new power in the hands of photographers, and that, intelligently used in conjunction with ordinary business enterprise, it is calculated to revolutionise the business experience of the winter months.

GUNCOTTON.

LIGHTING THE SITTER.

PHOTOGRAPHY may be studied both as a science and as an art. Science gives us technical excellence; art introduces beauty, grace, and feeling into our work. The photographer of olden time devoted all his energy to the technique; his ambition was the production of a sharply focussed negative free from pinholes, comets, smears, and fog. The camera artist of to-day leaves much of the science to the manufacturers, who supply him with perfect lenses and unimpeachable plates; and he in his turn studies the posing, lighting, and general arrangement of his subject in order to satisfy an exacting and critical public.

The posing and lighting of the sitter, whether regarded from a scientific or artistic standpoint, is a matter which well repays any attention and thought bestowed thereon, for upon them depend

almost entirely the degree of personal beauty and expression of the features portrayed. Many a photographer has wondered why his customers so frequently complained of the sad and heavy aspect of countenance shown in his pictures; he remembers telling them to look pleased and gay—and they apparently did so. Sometimes the mouth seems all right, for the corners are well turned up in a forced smile, while the brow is heavy with care, and the young sitter has the worn aspect of age.

Retouching does not put matters quite right. It will remove wrinkles, and make the face as smooth and round as an apple, but the truth of the portrait is generally affected, sometimes becoming so marred that the picture appears like another person—a sort of cousin with strong family resemblance.

The bad poser would photograph Mr. Punch with his distorted nose in profile, producing a caricature; the good poser, by taking a front view of his comical highness, would produce a portrait of a genial jolly fellow, with a nose apparently not much larger than the average.

The bad "lighter" would take a person possessing cheeks deficient in plumpness with a good strong top light without reflectors, thereby representing him in his photograph as a broken-down individual who had been imitating the doctor who fasted forty days, and who had thereby drank deeply from the cup of sorrow.

The good lighter would take the same person with light falling nearly horizontally from a position between front and side, with plenty of reflected light from other directions, making the face appear plump, the expression almost merry, and the eyes sparkling with health, and this without retouching.

These examples illustrate the well-known fact that upon the correct adjustment of the curtains, reflectors, and the interior of the studio generally depends the success of a portrait. The professional, working from experience and the recollection of past failures, though he may not inquire into theory much, produces good pictures; the amateur, taking his portraits in different places, and under varying conditions, finds most need of a few hints concerning the principles of lighting.

Outdoor portraiture has some advantages in consequence of the light being unobstructed by the glass panes, window-bars, curtains, and walls necessary in a studio. These advantages consist of a brief or instantaneous exposure, with a corresponding absence of blurring-through movement, fine definition of the details, owing to the small stop available in the lens, and the bright and clear appearance of the print generally, due to the use of landscape lenses having few reflecting surfaces. But outdoor work has its disadvantages. We cannot usually alter the lighting without an entire change of scene. If the top light is too strong the subject can go into a doorway, which gives probably too dark a background. If we move under some trees the lighting may be too equally diffused, and as we cannot control the clouds or direct the sunshine, we have to take the lighting as we find it, and content ourselves with a bright negative full of detail.

In a studio, or in a room possessing a large window, we can alter the lighting, but we are obliged to use a lens of large aperture and rapid plates, with occasionally forced development, for with slow lenses and plates we require a head-rest—an instrument of torture to many, who, when their heads are placed between its metal jaws, and their necks have become stiff or half paralysed by the constraint, are told to look pleasant. If we possess a studio fully furnished with windows, blinds, and reflectors, we can take good portraits therein, provided we understand the principles of lighting.

The most difficult feature to render satisfactorily in a portrait is undoubtedly the eye. The eye-ball, as everybody knows, is globular in shape, approaching whiteness in colour, and it has a bright, polished surface. Light falling upon the eye is partly reflected from its surface, just as it would be from a convex silvered mirror; this reflected light gives the bright speck usually seen in the eyes of portraits. If this point of light is wrongly placed, or if there are two equally distinct specks instead of one, the portrait is a failure, for when this is the case we have the effect of either blindness, squinting, an unpleasant expression, or a dissimilarity between the two eyes. To photograph the eye properly, it is not sufficient to show the outside shape, for then reflections would be of little moment. The interior of the eye is of as much importance as the exterior; we should be able to look through the cornea, to see the iris and its central opening—the pupil. In order to show the pupil as a black spot there must be an absence of reflected light from the centre of the cornea; and to see the iris in whole or in part there should be a total or partial absence of reflections from the rest of the cornea. It is the variation in the colour of the iris which produces the different varieties of eyes—blue, grey, black, brown, &c. Grey and black eyes give little trouble in photography; brown eyes appear too dark, and blue eyes too light,

Brown eyes can be corrected in the negative by careful retouching. Blue eyes cannot be assisted much in this way, but by cutting off reflected light from the cornea we may produce a representation which will require very little touching up in the print.

ALBERT W. SCOTT.

ENLARGING METHODS.

II.

THE general features and principles of the apparatus employed for purposes of enlarging were much about the same in its infancy as those embodied in the instruments made use of at the present time. They were, however, of a less complex order and of ruder construction, as sun and daylight were only then the illuminants at command, magnesium not coming into use till later, and other artificial lights were not of sufficient power to be of use with the slower plates and less sensitive materials then available for the purpose. The most expensive and best-known form for direct enlargements on iodised paper, with gallic acid development, was the arrangement known as Woodward's solar camera, now obsolete, or, at any rate, only to be met with in very old establishments, and there only as a curiosity. It was fitted with a large condenser of the nature of a bull's-eye for concentrating the sun's rays upon the negative, while it was necessary to keep this thin and full of detail to avoid the tendency to harden the powerful light and weak materials favoured. This instrument may be considered as the progenitor or type of the modern and more refined means of employing artificial light for the production of enlarged photographs as now obtained in the lanterns and cameras especially constructed for the purpose. Some of these are very elaborate and perfect, and one might expect to see great advances in the quality of the work over that of earlier periods when instrumental difficulties were greater.

Quantity, however, and speed have it, and seem to be more satisfying to modern needs, and likely to promote free circulation of pictures upon the walls of the purchasers instead of the production of works of art of a durable character. Direct enlargements, apparently, conduce more to the filling of the pockets of the firms who produce them than to the credit of photography.

The arrangements necessary for making enlarged transparencies and negatives by daylight are now, as formerly, of a simple kind, especially when a room, or part of one, with the use of a window to be darkened at will, is at the service of the photographer. A frame or table on which a camera can be placed to slide towards an aperture in the window shutter, and adjusted at such an angle that it points to the sky, with an extension of the frame to carry a second board or easel perpendicular to it, is about all that is required in a small way, and is a fair illustration of the principles involved in the construction of the more elaborate and expensive kinds used by the first-class professional enlargers, upon which anything can be done from the smallest locket to life-size, and upon which adjustments of great accuracy can be accomplished in a short space of time. I have several such cameras, and one in especial upon whose easel I can adjust and focus a midget or a 30×24 with the greatest ease, rapidity, and certainty. Cameras of such a range are necessary to these firms on account of the great variety in the size of originals and what is required from them which constitute the orders they book; the assortment being so great and irregular that tables of enlargement are but little use, a defect of assistance that must be counterbalanced by improved means of adjustment in the cameras, whereby the changes in question may be immediately carried out in accordance with the judgment and experience of the operator, whose constant practice teaches him what to do when the instructions accompanying the negative are made known to him. Where it is simply to go from one common size to another, reference to tables or notes saves trouble. It is well on any camera, even of the most makeshift sort, to lay off on the table or frame supporting it, and upon which it slides, a scale in inches and feet, to enable the positions of the lens and easel in respect of the original negative to be noted for future use. The common requirements—as *carte-de-visite* to cabinet, whole-plate, &c.; cabinet to whole-plate, 10×8 , &c.; and so forth—may appear in the list, with their respective positions in inches marked against them. The table may be either calculated by the usual formula for the lenses in use, or arrived at by fitting plates of the sizes named into the negative carriers and enlarging them to the sizes of which particulars are needed. It is a rough-and-ready way, but is quite effective. Indicators are only necessary when lenses of all descriptions are employed in the camera. They may be of use in clubs or enlarging rooms open to all—that is, if the frequenters of such places understand them—but are not of much account on a professional photographer's premises, who has no space for ornaments, and no time

for fads. A pair of compasses, a foot-rule, and a quick method of shifting the different parts of the camera, in addition to the above table, will consume less time and brain, and be found more satisfactory.

These remarks only apply to the ordinary enlarger's and copist's work in portraits and landscapes where micrometrical accuracy would be simply labour thrown away. When it is a question of great nicety, as in dealing with the enlargement or reduction of drawings, maps, and plans, then too much pains cannot be taken to ensure exact knowledge of the equivalent focus of the lens in use, and its position in respect of original and sensitive plate to enable the variations of scale it is desired to reproduce these subjects in to be faithfully performed. In this class of work no rule-of-thumb or makeshift appliances will do. Something definite is needed, and definite means must be employed to obtain it. It is therefore essential that the enlarging camera be well constructed, and that the principal planes perpendicular to its base carrying original lens and sensitive plate respectively may in sliding keep true parallelism with one another, and have such adjustments to them that any failure in this respect may be detected and remedied; for let the camera be ever so beautifully made and exactly right at the outset, it will not be long before the means of correction prove their value. Photography with apparatus of this description is slightly different to that of snap shot with a hand camera. "Nine-bob-square" is "out of the running," and the tendency to fad does not come, because there is ample exercise for one's thought, skill, and patience without it.

The earliest artificial illuminant for enlarging which was at all common was that of burning magnesium, and the best-known form of lamp in which it was consumed as a ribbon being Solomon's. It held the field for a period of years when direct work on iodised silver paper was the means of supplying the demand for cheap enlargements, but was afterwards superseded by the limelight, when the carbon process requiring enlarged negatives began to take hold and come into great prominence. For this form of light for enlarging there is much to be said. It is of a very high quality, and now the means of producing it have been so much improved, it is simple and safe and not at all costly. Its rivals are, the electric arc, the expense of the installation of which will prevent its becoming common, at any rate, till electricity is "laid on," and paraffin oil, within every one's reach, and quite suitable for the gelatino-bromide and direct silver work, whose age we are now delighting in. The employment of petroleum has caused the enlarging camera to assume the appearance of the optical lantern, now so well known as to need no further mention.

The best lenses for enlarging are those of the rapid rectilinear type, doublets, triplets, and portable symmetricals being equally useful when there is an abundance of light, as they are somewhat slower in action. Whatever be selected, see that they are quite free from spherical aberration and capable of giving an absolutely sharp image on a portion of the plate, say with a $\frac{1}{2}$ stop. Lenses by first-rate makers vary, therefore it is well to learn an instrument thoroughly, that its powers may not be exceeded. I have two of one kind, by a first-class optician, made at periods widely separate. They are not of equal merit, the younger one being a great deal behind its elder, its image not being absolutely sharp under any circumstances where the middle-sized stop is exceeded. The defect is only trifling, and would not be noticed except in the trying conditions of reproducing, where the test is a severe one. When convenient it is a good plan to enlarge or copy the negative by the lens with which it was taken, taking the precaution to keep their relative positions the same; that is, the back combination towards the negative. The lens then, by re-passing the image, corrects any defects it had previously caused. Distortion, as produced by single lenses, may be thus remedied. Portrait lenses may be employed for bust pictures, but are scarcely to be recommended for those covering the sheet. JOHN HARMER.

A PERMANENT TEN PER CENT. HYDROQUINONE FORMULA.

[A Communication to the Photographic Club.]

THE subject of hydroquinone has been so much written and talked about that it is pretty well done to death by this time; but as the season is just upon us when we shall all be ready to rush out into the country to secure some fresh scenes which perhaps may have escaped our notice before, this, then, will be the time when hydroquinone will have to fight its brother on the battle-field of developers. I am not going to say at present that I prefer this chemical to pyro until I have had greater experience in its use; but when I use pyro and ammonia, or soda, I am inclined very often to cry out, "Good old pyro!" and I am sure many besides myself here will agree with me that it

requires a good deal of beating. However, in many hands hydroquinone is capable of producing quite as good results as any other developer, and, moreover, it has the quality which I am sure many will hail with delight, that it does not stain the fingers, and the negatives produced by it are of a brilliant and clear character, which makes them extremely useful during the dull winter months for quick printing.

If the chemistry of hydroquinone I do not intend to touch this evening, as it is quite outside my sphere. I must leave this side of the question to my friend, Mr. Levy, who has already given us valuable and interesting information respecting its nature, and who has, I know, a great deal more to say respecting it.

Hitherto, all the formulæ that have been published have been rather too bulky; that is to say, that it was impossible to get a very large proportion of hydroquinone into solution owing to its being sparingly soluble in water. This, of course, is a serious drawback, not so much to a portrait photographer as it is to the tourist, who, of course, requires that everything should be in as concentrated a form as possible.

In some of the early formulæ, alcohol has been recommended as a solvent for hydroquinone, it being extremely soluble in the liquid, namely, to the extent of about thirty per cent., but it has this drawback, that the solution soon becomes a very dark brown colour, almost worse than pyro in the same oxidised condition. In the formula I have just perfected, alcohol is still the liquid in which the hydroquinone is dissolved, and in order to preserve it from oxidation I employ sulphurous acid, which appears to keep it good without any change at all, but I can only speak from three months' experience at present.

As it was the wish of the majority of members of the Photographic Club that some reform should take place in the weights and measures of formulæ, I have taken this opportunity of giving the proportions of this new ten per cent. hydroquinone in the French measures—viz., grammes and cubic centimetres—pending their decision as to something better; although extremely convenient and easy in use, I am afraid it will be a long time before the method becomes general, because as long as things continue to be sold by the ounce, so will formulæ be given in the same.

The formula stands thus:—*

Hydroquinone	30 grammes.
Spirit (meth.)	100 c.c.
Sulphurous acid	100 "
Water, sufficient to make	300 "
Sodium hydrate	30 grammes.
" sulphite	30 "
Water, to make	300 c.c.

Take three c.c. of each solution, and fifty c.c. of water.

You will notice that I have endeavoured to keep the proportions as round numbers as possible. There is nothing I abominate more than a complicated formula; the simpler it is the better, not only in chemicals, but also in the proportions.

The strength I have given will develop a plate in about five minutes with normal exposure. The addition of bromide is not necessary. (I may say here that I have experimented with Thomas's plates only, so cannot say if the developer is suitable for other plates.) Potassium hydrate may be used instead of the sodium, but then a larger proportion must be used. By so doing you naturally get more sulphite of soda as well; this tends to keep the developer clearer for a much longer space of time. I may just say that the sulphite may be left out entirely; although the solution discolours a good deal, the appearance of the negative is just the same as though sulphite had been used.

I feel I have sufficiently exhausted the subject, at least from my point of view, as writing a paper to me is not such a work of love as carrying out experiments. However, one is always well repaid by the attentive manner in which a paper is received by members of the Photographic Club.

J. B. B. WELLINGTON.

* For the convenience of some of our readers we have converted the formula into English equivalents:—

A.	
Hydroquinone	462 grains.
Spirit (meth.)	34 ounces.
Sulphurous acid	34 "
Water, to make	10½ "

B.	
Sodium hydrate	462 grains.
" sulphite	462 "
Water, to make	10½ ounces.

One part each of A and B to seventeen parts of water.—ED.

SKIES.

Why is it that the average photographer pays so little attention to "skies?" There is nothing that gives such a charm to a picture as a suitable and picturesque sky, and yet we see so many landscape and architectural subjects with the plain white skies once so popular—when a "clean" sky was looked upon as proof of technical excellence. A photograph with such a sky is like a song without accompaniment—it may be good technically and in an artistic sense, but it lacks the charm of music, for a well-graduated and properly lighted sky is "music" to a picture!

There are many difficulties in the way of obtaining a good sky on the same negative as a picture; but there is absolutely no difficulty in obtaining suitable skies on separate plates, and utilising them by combination printing; this is even now considered as illegitimate by a few photographers, but there is no sound reason for their objections.

Even when we find photographers who carefully print in skies they are oftentimes of such a "woolly" nature as to damage rather than improve the picture, and it very often happens that the same sky negative is made to do duty for a whole series of views—this is "too much of a good thing!"

Who can look upon the beauties of even an English inland sunrise or sunset without feeling a sense of the beautiful and a keen appreciation of the variations of light and shade? even a stormy sky has its delights, with its white, fleecy lights and heavy masses of black shadow.

Many negatives which are only passable may be made to yield charming prints by the addition of a beautiful bit of "cloudland," just as the commonplace words of a song may charm the hearts of its hearers by the sweet melody of appropriate music. Many well-known pictures owe their popularity in a great degree to the "music" of their skies, just as many popular songs owe their success to their music; therefore it behoves us to look to our "music," if photography is to take its proper place among the older arts.

OXONIAN.

PSYCHIC PHOTOGRAPHY.

We are slightly at a loss as to formulating the position one might reasonably hold concerning Psychic or Spiritualistic Photography. But we believe it may be done in this way: Some believe that death does not end all, as regards human beings at any rate, but that after passing through that experience known as death, men and women still live, and may make themselves manifest under certain conditions. This, we take it, is Spiritualism, especially as distinct from Materialism, which recognises no existence after death.

The spirit-body is supposed to be existent, and capable, under certain conditions, of making itself visible, if not to the visual organs of the observer, at any rate to the photographic plate. We very well know that there are invisible as well as visible rays of light, and Spirit Photography is assumed to be founded upon the emanation of rays invisible to the spectator, but nevertheless existing—in short, the rays which are ultra blue, and which all scientists recognise as possessing chemical power without being able to impress themselves upon the sight nerves of a normally constituted human being.

Photography has long been said to afford the means of determining the existence of such invisible entities—that is, if these be present when the photographic operation is going on; and just so far as photography is supposed to conduce to this end, and not one step further, do we permit the discussion of "Psychic Photography" in our columns. We don't want hypothesis or opinions, but well-attested records or results of experiments.

A correspondent of the *Birmingham Daily Gazette* has interviewed Miss Power, and having evidently made himself intimately acquainted with all that appeared in our pages ere the correspondence relative to Psychic Photography became so heavy and voluminous that we had to close it, has written a very long account of the subject generally, and this interview in particular, from which we make a few extracts.

"The Society of Psychic Research has taken up the matter, and appointed two of its members—Dr. Myers and another—to interview and examine Miss Power. Visitors come from all parts of the country in the hope that Miss Power may be able to secure a photograph of their dear departed relatives or friends. Letters arrive from all parts of the world making anxious inquiry touching experiences in the life to come. Miss Power courts inquiry, and rarely refuses to give an audience even to the most sceptical. The psychic photographs—some of which have been developed by Mr. Whitlock, of New-street—are taken in a small upstairs room, which one can cover in a couple of strides. The camera is placed in position, and focussed on or rather slightly above the chair on which Miss Power is to sit. The window is heavily draped, the fireplace screened, and the room

made perfectly dark. Then Miss Power and visitors take their seats and maintain absolute silence and stillness, in order that the air in the room may become quiescent. When all is deathly still and silent, the Ilford quarter-plate, which has been previously placed in the slide and uncovered, is said to receive the image of the spirit or spirits floating in the room. Then a magnesium light is burned in order that visitors may see that there are no strangers or trick-forms present, and the plate is immediately developed. As the burning of the light was considered by some visitors sufficient to cause a cloudy appearance on the negative, a few had been taken in absolute darkness—with the same result. The spirits mostly have a nebulous shape, and seem draped in a variety of night-dresses. One spirit looks like a well-to-do gentleman with a handsome beard; another resembles a woman of sixty; a third is a girl of sixteen, of delicate figure. Believers and unbelievers can buy them at a shilling each. Miss Power invites mediums who possess a camera to buy a box of plates and try to photograph their intimates in the other world. She says there is no reason why any one should not obtain good negatives."

After describing some "manifestations" said to take place, the interviewer continues:—

"But to return to matters in which the public are more closely interested. Miss Power is interrogated as to why the challenge of the editor of THE BRITISH JOURNAL OF PHOTOGRAPHY has not been accepted. Her reply is rather startling. 'Dr. Norris, you know, is the president of the Birmingham Photographic Society.' 'Yes, and after the intimation in the JOURNAL he probably communicated with you?' 'No, he did not. You see, he is a spiritualist, though he doesn't publicly avow the fact. He effects his cures by the aid of the spirits; he has earned his position by spiritualistic means.' Which delightful revelation will probably startle Dr. Norris almost as much as it did the interviewer."

On this "delightful revelation" we have merely to remark that if the spirits, either directly or indirectly, had a hand in enabling Dr. Norris to make his great discovery of photographic dry plates forty years ago, then for once, at any rate, they have done a good thing, and one which entitles them to the lasting gratitude of photographers.

A CHAT ON DEVELOPMENT.

THE value of the varied manipulations in the production of negatives has been immensely enhanced since dry plates have come into general use. Speaking broadly, comparatively little latitude is allowed in the three main operations, viz., lighting, exposure, and developing, which very largely accounts for this. Two or three seconds more or less in the exposure did not, as a general thing, materially affect the negative in the old wet plate days. The lighting, again, did not require the same nicety in modelling, and developing was far easier in many ways: one great reason being that intensification was so simple a matter, which it certainly is not with dry plates.

Then, again, dry plates are very tricky. Without wishing to say anything unkind about the manufacturers of them, it is an undoubted fact that to get two batches of the same maker's plates exactly alike is almost an impossibility. They do vary, and that very considerably sometimes; and what has to be done is to so regulate things and apply methods that uniformly good results may be got.

Sometimes, for instance, they dry up very dense, at others losing rather in density; now the film is more di-actinic and looks really "thinner" than "printably" (to coin a word) it is. And reasons might be multiplied to prove that they are what I termed them. Well, it follows that a long and careful experience is a *sine qua non* to successfully work them—I mean "commercially" successful, where nearly every "shot" tells: not after the manner of many who do not pose as amateurs, who think they have done big things if they get a decent negative out of every three or four exposures, and that by a wretched "fuke."

Without doubt a good "developer" (using the word as a personal appellation) deserves well of his profession; and where he holds the post as a distinctive office, it is hardly fair to relegate him to a position inferior to the other operators. He is a man of skill; skill acquired by an unstinted use of the faculty of observation and unremitting care, which by mitigating studio difficulties makes the work go "merrily on." His work seems to be done by a sort of intuition; he knows when to send the developer over the plate with rapid "swirls"—by so doing brightening up the lights and avoiding flatness—or by a gentle undulatory movement coaxes out the details; or, again, sends over the developer with a scarcely perceptible movement in order to prevent "hardness"; now "tilting" and manoeuvring so that a defectively coated plate may be circumvented and uniformity of density obtained.

So much in fact can be done in developing, either for good or for evil, that too much care and attention cannot be devoted to it. It is not the simple operation of "only just pouring on the acid" that one

hears from time to time from the lips of the knowing "amateur," and the spirit of which too many professed photographers exhibit, if one may be permitted to judge by their manipulating and the results thereof. No, there is a good deal more than that wanted, even supposing all things are favourable. The light and subject have always to be considered, as well in the developing room as in the studio. In consequence of this fact it has always seemed to me that those who develop at the time of sitting are in a position to attain—well, if not better, certainly more uniform results than those who do not, and who defer development until the end of the day's work, for it is hardly possible to remember the conditions under which all the exposures were made; but being a necessity with very many, carefulness and quickness of resource are imperative.

With many operators there is far too much hurry and flurry. It may be a fresh batch of plates are commenced; if the picture flashes out quickly they (in nine cases out of ten) jump to the conclusion that overexposure is the cause; resort to restrainers or condemn; exposure again, cutting down exposure, and are astonished and disgusted at a meagre, miserable-looking negative. One occasionally does get a batch that develop in this way, but they will yield good negatives granted the image does flash out more quickly than is liked; still if correctly exposed detail will not be lost: they will gradually increase in density, further detail does not come out, and as a consequence the image will not flatten nor the shadows fog. With a plate of this kind one thing must be very carefully guarded against, and that is overdeveloping. "Piling" up rather slowly they are apt to look much thinner than they really are, and as a rule the film is extremely di-actinic.

Some samples, again, develop in a way exactly the reverse of the foregoing: they come up very, very slowly, and continue to give detail the whole time of developing. They would be voted a nuisance by any one in a hurry, but the results are good. With these, again, an impatient man might conclude that they were "slow" (in exposure), and that more time was wanted. Arriving at that point he might decide to condemn or consider it necessary to "dose" with ammonia to "hurry" it up. Such treatment is decidedly to be condemned, as it is detrimental to good work. Naturally enough the stronger lights are seized upon with avidity, and before the picture is fully developed the finer gradation and half tones are ruined. Plates have got their peculiar ways—well, try and find them out, and let them have them so long as satisfactory results are at the end of them.

Plates that develop rather slowly all round—that is, detail comes slowly and density also—are deservedly the favourites with the great majority; for the negatives, as a rule, are better than those on the very quick or extremely slow. They are well under control (a great desideratum), and density can be judged to a nicety.

The great want and the most difficult thing to get with dry plates is really good modelling. This can only be done in lighting, although an equal care is necessary in developing: under and over development is so easy. *Apropos*, there is an immense advantage in sticking to one good make of plates (or two or three at the outside), as all their peculiarities and variations become known and (what is more to the point) the modes of treatment rendered necessary in consequence. There are restless spirits who are always trying something new, either in plates, developers, or fad of some sort: they are never content, their work is variable (what wonder?), clients are dissatisfied, and re-sits multiply alarmingly. Now while it is quite right the *last* new make should be tried so that the *best* may be found, or at least justice done to all competitors. But where much egregious folly is displayed in clearing or running out of the old reliables, instead of continuing their use until experiment has found a better. These experiments, again, are frequently conducted very unfairly and in a slipshod way. Old developers and methods are used, and the endeavour made to fit them to the new plates; as a result many good plates are condemned, and the spirit of unrest lives on.

With regard to developers themselves, it will generally be found that the maker's formula is the best; modifications have, of course, to be made now and then. To cite a case in point. A few years ago I was under the necessity of returning a couple of grosses; the negatives were simply execrable—flatness, halation, everything that was bad; variations of the old standard developer—and in the exposing were equally useless. I had a few left, and during the slack season I made up a developer "out of my head." It was very simple, being as follows:—

Liq. Amm.	1½ drachm.
Br. Amm.	1 " "
Water	12 ounces.

With this I used equal quantity of water, adding a few grains (to

ounce) of dry pyro. The results were charming, and I sadly regretted I had not the sundry returned dozens in stock. This developer, however, proved quite unsuitable for the ordinary quality of the same plates. At another time I used half ordinary and half sodic sulphite with good results.

It is necessary to know something of the properties of the chemicals used, and with that knowledge a little common sense will overcome many worries and difficulties and lead to greater success. I do not know what the opinion of others may be, but I do incline to the bromide of ammonium rather than to the bromide of potassium as a restrainer. It seems to admit of greater delicacy of half tones—gives more half tone in fact—the image does not seem to “fill up” or “block” to the same extent, even when development has to be prolonged. There are advocates in abundance for the sulphite of soda developer, but invidious comparisons are unnecessary, good results are to be got with almost any formula, but like many other things much depends upon the using.

More directly to the subject. If the negative, despite its want of vigour, gives plenty of half tone and clear shadows, then an increase of both pyro and ammonia should put matters right; in obstinate cases dry pyro might be better than usual “stock.” If, however, the negative, in addition to thinness, lacks half tone, and the shadows are hazy and dirty-looking, pyro must be increased, but using normal quantity of ammonia; or, that failing, the bromide might be increased. The latter method, however, is rather hazardous as “sootiness” is not an infrequent result. “Another way” (pardon cookery-book parlance) is to flood with pyro first for a minute or two before adding ammonia; or should they be plates developed with ordinary pyro and ammonia, it is not improbable that if the sulphite developer be used better results will be got. If, however, there is an inclination to hardness, half and half of developers. Sometimes there are plates which will give intolerably strong contrast—they are rare it is true, and well that they are, for they require a lot of very delicate attention before decent results can be got. Exposure should be lengthened as much as possible, even until the deepest shadows are *slightly* hazy; developer also must be reduced. First try usual quantity of ammonia and less of pyro; if, however, negative lacks modelling use less than normal quantities of both. Immersing in water for a minute before developing will sometimes improve them, or even flooding with ammonia first; this latter wants great care.

Most plate makers recommend immersing in the alum bath before fixing, simply as a precaution against frilling. I do not wish by any means to pose as a “quidnunc,” but I certainly do think the alum bath plays another and not a less important part than preventing frilling. Sometimes the result is beneficial and sometimes it is not. With some it acts as a kind of “fixer,” rendering the unfixed image more permanent, and imparting good qualities to the film. On others, again, it has an effect quite the reverse and impairs the quality. One thing, however, is important—the alum bath should be weak and *not* of the same strength as that used after fixing; for if the strong is used it has a deleterious effect (at least in those cases I have noticed), robbing the film of good printing quality. I do advise operators to try the effect of immersion and of non-immersion, and so prove for themselves which method is the better for their own particular plates. I use a deservedly popular plate and *always* immerse prior to fixing, as I find without it the negatives are not anything like so brilliant. On the other hand, I have others (not same maker's) which puzzled me terribly. They worked well and quickly, and everything looked perfectly satisfactory until they were in the fixing, when, horrors! they were all streaks and patches, took an unheard-of time to fix, and when they were fixed there was a regular network of transparent markings rendering the negative valueless. I could not understand it a bit, as I am always careful to wash the plate well after removing from the alum. One day, however, I cut an exposed plate in two, and after developing put one half as usual into the alum and the other direct into the fixing; the latter was perfect, the other came out exactly the same as the others had done. I offer no reason for this: I simply relate it. The moral, however, was very obvious.

It is always advisable to bring up the negatives a *little* more than full printing density, but of course *not* to the “blocking” point. Plenty of “body” is admittedly a *sine qua non*, but that need not be at the sacrifice of either detail or half tone. A trial or two will decide upon the amount of extra density; then to reduce with the alum, citric acid, and sulphate of iron “reducer” to correct printing density. It will give a beautiful blending of shadow and high light, capital printing quality, and, in addition, will obviate and consequently save a good deal of retouching. The “reducer” with sulphate of iron is preferable in the majority of cases—the lights seem to be kept purer and brighter. It may be used the full strength for

obstinate negatives, or reduced for those that require little more than the staining, a simple flooding being sufficient. There are plates that are better without having to resort either to reducing or staining, such as those which give delicate yellowish films; robbed of their “natural” colour they seem to lack life and vigour, and the prints are “leadeny” looking.

A little hint *re* really obstinately thin negatives and also for copying. Sufficient density cannot be got by the ordinary methods: use dry pyro with usual ammonia for developing, and *before* putting either into the alum or fixing bath (the former bath may be omitted) let them stand for about ten minutes or so; the result will be an intensely yellow film, one which will give bright prints. Exposure to daylight for a minute or two sometimes improves a negative inclined to dirtiness in the high lights, especially those developed with the sulphite developer. I stumbled across the “wrinkle” some years ago. I had a great number of sitters and could not possibly spare time to develop, so had to develop all together. I had to keep one or two plates waiting before I could put them either in the alum or fixing. The result was deplorable, such a density I could not get rid of with the strongest reducer. All the other negatives were perfect, so that I read the cause at once, and have profited by the experience many a time.

Very much more might be written on so vital and engrossing a subject, but I trust the perusal of the few notes I have submitted will tend to create a more intelligent interest amongst some of us in the little details of manipulation which dry plate photography demands, and also prove helpful (to some at least) to the attaining of every operator's ambition—a *good negative*.

WILLIAM SCHMIDT.

ART IN RELATION TO PHOTOGRAPHY.*

THE recognised leaders in art incur serious responsibilities, seeing that they have, as it were, the moulding of the feelings and ideas of those who trust themselves to their guidance; and how easy it is by dogmatic assertions of their own views to warp the judgment, to blight and chill the fervid aspirations of their pupils. It has often struck me that there is a very marked difference observable between those who devote themselves exclusively to artistic pursuits, and those who identify themselves with matters of a more scientific character. In the former there is a kind of Bohemianism and a manifestation of insipient lawlessness, call it devil-may-care if you like, which is quite refreshing to be brought into contact with, whilst the latter seem to partake more of a cold, arbitrary character of their own mathematical calculations.

All that glitters is not gold, and it is equally true that all which is pictorial is not art. Still, setting aside for the moment the question of art, it is by no means surprising that the practice of photography has endeared itself and become so popular with such a large section of the community as it has. This, of course, is partly accounted for by the fact that during the last few years the mechanical and manipulatory difficulties have been reduced to almost *nil*, so that now any one who possesses the smallest amount of manipulative skill is enabled to prepare for himself results which form at least pleasing reminiscences of places he may have visited, or reproductions of objects which he values. Indeed, it is becoming a common practice for the proprietors of large concerns to make it a special adjunct of their business plant, so as to utilise it for advertising and various other purposes. The professional photographer probably regards this movement as a kind of innovation upon his vested rights, and feels that his nose is being put out of joint; but if he finds he is getting too much spare time on his hands, let him, by a greater exercise of his artistic skill and training, bring it to bear more forcibly upon his professional work, and he will not find his occupation gone, but probably increased by his having raised himself upon a higher platform of art—for, depend upon it, there is still plenty of room upwards—and by so doing he will find that he will still be able to afford himself the luxury of a little bit of cheese to his bread.

I cannot allow this golden opportunity to pass by without breathing fervid anathemas at what I consider the most withering influence which has ever been brought to bear upon photography. You will have anticipated me when I say retouching, that insidious, treacherous photographic art, the older I get (and people tell me I am getting on) the more do I hold it in contempt. The introduction of albumenised paper, although hailed with delight by many, was, to say the least of it, a retrogressive step, but the so-called art of retouching, fraudulent and libellous as it is, has done more to degrade the art side of photography than all other abuses combined. The full power and capabilities of photography pure and simple, especially in portraiture, will never be developed until the almost despotic rule of this dangerous usurper is suppressed. Let us then have more genuine photography into which the art instincts of the photographer himself have been instilled—and the means at his disposal for assisting him in his endeavours are infinitely greater now than in days of yore—and we shall then find that there will no longer be the

* Concluded from page 165.

necessity for resorting to such mechanical and meretricious aids, and photography will rise with increased vitality into more elevated regions of art.

I would not have it supposed for one moment that I am indifferent to the advantages of art culture; indeed, I regard such gatherings as this as highly conducive to our best interests in that respect, the bringing together and contrasting one with the other the various examples of our work, as on this occasion, is not only pleasant and agreeable, but highly instructive and educational; and most sincerely do I appreciate, in common, I am sure, with all the other members of this Club, the warmth and geniality of feeling which prevails, as well as the willingness—indeed, I might almost say anxiety—to impart information one to the other upon matters connected with photography. The only regret I have is that, with hearts so expansive, our accommodation is not more extensive; but I still hope that in the not very distant future, to use a commercial phrase, this long-felt want will be duly met. Wm. Cobb.

LORD RAYLEIGH ON EXPERIMENTAL OPTICS.

III.

LAST Saturday the Right Hon. Lord Rayleigh delivered his third lecture upon the above subject at the Royal Institution, and said that in optics wave length is dealt with rather than periodicity of vibrations, because the latter cannot be directly measured as they can in the case of sound. The periodicity of waves of sound is readily measured by the aid of the siren and of other instruments. In experiments on sound the beat can be compared with the known rate of velocity of sound. With light, difference of wave length gives difference of colour, and the refrangibility of light depends upon wave length; the longer the waves, the less they are refracted.

In relation to the elementary phenomena of light, there is not much to choose in explanation thereof between the emission and the undulatory theories. No doubt the projection of shadows is more easily explained by the corpuscular theory, and that made Newton incline to it in the later years of his life. Sound waves are usually supposed to pass readily behind obstacles, but this is rather a mistake, because sound shadows can be thrown and made experimentally evident. The phenomena of the reflexion of light present no difficulty by either theory; the projectile theory does just as well as the other, and by it it is also necessary that the angle of incidence should equal the angle of reflexion. Refraction is not so easy to explain by the corpuscular theory, but Newton overcame the difficulty fairly well; it is necessary, however, to assume that light moves more rapidly in glass or water than in air. As this point had not then been experimentally decided, there was nothing to choose between the corpuscular and the wave theories, consequently so long as nobody wished to hold both theories at once, everybody was happy. Subsequently Fresnel and Foucault proved that in this matter the corpuscular theory is contrary to fact, so that no two theories are now possible on the subject. When light strikes glass a part of it is reflected and the other part refracted; in other words, it is divided. The wave theory lends itself much better than the projectile theory to the explanation of this phenomenon.

When we pass on to other phenomena there is no comparison between the two theories, and in relation to the colours of thin plates the corpuscular theory makes a very poor show. What happens when two trains of waves of the same length are superimposed one upon the other? When the crests of one train of waves tend to fall into the same positions as the crests of another train of waves the light is intensified, but when the depressions of one train of waves tend to coincide with the crests of the other train of waves the two influences neutralise each other, so that darkness is then the effect of mixing two lights of the same colour. There are intermediate positions in which the waves may meet, and the various relative positions are called "phases" of the wave, a term adopted previously in relation to the phases of the moon. The length of a wave fixes the colour, the height or amplitude of the wave fixes the quantity of the light. When two waves meet, and their phases agree, twice the amplitude is the result; when the phases are opposed we get nothing.

The colours of thin plates were known in ancient times, and were tolerably well described by Hooke, the predecessor of Newton. Then they were described by Newton himself, and subsequently by Young, in whose hands they became the determining point of the wave theory of light. When light strikes a sheet of glass, part of it is reflected from the front surface and part from the back surface. If the plate of glass be reduced to such thinness that one wave is retarded and thrown behind the other, colour is the result when white light is used. When homogeneous light is used alternations of light and darkness occur. The speaker here performed Newton's experiment, in which a slightly convex lens was pressed upon a flat piece of glass, so that a circular wedge of air was formed between the two pieces of glass, and so thin as to present rings of colour when white light fell upon it. When red light was made to illuminate this arrangement, and the image of the concentric rings was projected on the screen, the rings appeared red and black; with green light they were green and black, and of a different diameter, for which latter reason colour is produced when white light is used in the

performance of this experiment. The space in the centre of the rings was dark at the place where the lens and plate were in closest contact, and where the plate of air was almost of no thickness at all. At that place we might expect to find the light brightest. This, in Young's days, was a great difficulty; he explained it, but was not understood by his contemporaries. In the phenomenon there is a kind of reversal in the circumstances; in the one case reflexion is from the denser to the rarer medium, and in the other from the rarer to the denser.

Soap films, as in the soap bubble, best exhibit the colours of thin plates. The speaker here made some thin circular soap films supported upon small metal rings. He illuminated each film by electric light, and projected an image of it upon the screen, so that as its thickness became less by evaporation, and colours appeared, they could be seen by every one in the theatre. He said that some experimenters mixed glycerine with their soap solution to make the films more permanent, but glycerine tends to absorb water from the atmosphere and to make the films thick. It was best not to use glycerine when experimenting with soap films on the colours of thin plates. He then thinned down some of these films by Brewster's method of causing to play upon them a steady jet of air from a nozzle and tube connected with a weighted bellows. The air increased evaporation from the surfaces of the films, with the result that gorgeous displays of colours were seen upon the screen. Some of the colours were so remarkably strong that it is scarcely surprising, he said, that Brewster, towards the end of his life, broached an extraordinary theory that the soap bubble in some way secreted colours.

Lord Rayleigh said that, for the sake of convenience, the term "ray of light" is frequently employed, but it is doubtful whether it is legitimate to use the word "ray" at all. He frequently in the lecture employed the phrase "train of waves."

TRIALS AND TRIBULATIONS OF THE PHOTOGRAPHER.

[A Communication to the Society of Amateur Photographers of New York.]

NOW, ladies and gentlemen, I have been asked to talk on the *Trials and Tribulations of the Photographer*. Well, I stood it for forty-one years, and I should be very sorry to undertake to tell you all of them. It might take me another forty-one years to get through with it. But, fortunately—or unfortunately—I generally try to make the best of everything, and what might have been a trial to many I endeavoured to laugh off. I was told that the business was very unhealthy, but I tried to laugh and grow fat. I commenced at a hundred and twenty-five pounds and finished at two hundred, so that it was not very unhealthy in my case.

In speaking of the Daguerreotype (and we have just listened to a very interesting and a very excellent address), I want to say that I was a practical Daguerreotypist from fifteen to seventeen years, and in looking over some old books of account I believe that I made and sold to the public 200,000 pictures, so that I am something like the boy eating pie—I have had an enormous experience.

I well remember the 15th day of October, 1846. I placed at my door a little frame. I think it had four pictures in it, and at that date the people were very much interested in the Daguerreotype. It was the "wonderful silver picture," and you would hardly have time to hang your frame out in the morning before there would be large crowds around it, all anxious to get a sight at the wonderful picture; and at that date a man who made a good Daguerreotype was looked on as a scientific man. He was not a mere "machine worker," as photographers have got to be called to-day.

I believe that, not only in talking of photography, but in writing of it, there is too much latitude nowadays and too much fancy writing. It is not practical enough. It is quite amusing to me to read six, or eight, or ten columns in one of our photographic journals written by some young man who has never stood under a skylight, and yet he gives us directions as to how it should be done, and how to do it. Place that same man under the skylight and let him wait all day upon eighty people—all kinds of people, men, women, and children—and let him do that for each day, and there would not be enough left of some of these writers to make a respectable funeral when night came. I am glad I had a subject. I will try and stick to it, but I am afraid I will not.

I should be sorry to speak about any new developers. I think there are 2163 or 3102—somewhere along there—and each one susceptible of two or three changes. I have some compassion on the brain of amateurs, as I understand the lunatic asylums, like the learned professions, are crowded. And then, again, I have been a fool if I would not recommend before this audience somebody's plates; I am too much of a coward for that. There are too many good plates in the market, and I would not dare to recommend one man's plates for fear I would never see any peace and comfort the remainder of my days from the rest of the makers. In short, I would rather not do it. As I say, I am too much of a coward for that.

I saw a pretty good Irish bull the other day. It seems that Pat came very near being killed, but by some dexterous movement he saved his life and got away. Some one said to him, "Pat, you are a coward." "Well," said Pat, "I had rather be a coward for ten minutes than be a dead man all the rest of my life." And so it is in regard to the recommendation of any specific plates, for if I did I would never see a minute's peace.

But there is one thing I would say, and with all the nonsense I want to mix a little sense: Get a good reliable plate and get a good developer and go to

work and master them. Then, after you have mastered them, if you can find some changes that are going to be better, all right; but if you are going to follow each and every one's make and each and every one's suggestions, you will never make a worker. In the old days of the Daguerreotype we had one developer, and I think sometimes to-day it would be a good thing if we never had but one. There would not be half the changes and mistakes and half the plates spoiled that you see to-day.

I remember once a very singular thing. We used to have to go out and take sick people. We had a little developing box that I could carry under my arm—the camera and the whole thing, and the mercury for developing the picture, and a lamp to heat it; and the mercury after use we poured out from the corner here into a little bottle. I went one day and took some pictures of a sick lady, and when I came to pick up my things to go home I found I had not put my mercury in the bath at all, but my pictures came out just as well. That was a very singular circumstance to me, but I accounted for it very soon: there was enough mercury in the iron developing box to develop a picture, but I never made that mistake afterwards.

In the olden time the public had a very hazy conception of the process of making a picture. The people at that time knew no more about how the impression was made, and not so much as the most ignorant do to-day; and they think if the machine is good a good picture is the result, and that is all they know about it. And in those times they talked in this way: One man would show his superior wisdom (he was telling the men who were around him), "You look in the machine and the picture comes, if you look long enough." Another one says, "It is not so much the looking, but the sun burns it in when you look." Another one settles the whole thing by saying, "It is not so much the looking, but the plate itself is a looking-glass, and if you sit in front of it long enough your shadow sticks on the plate." I have heard those very remarks made myself.

We had a great many pupils in those days, and everybody who could not succeed in something else started to learn Daguerreotypy, and the first question the pupil would ask was, "How long does it take?" I was forty-one years at it, and I never learned it all in that time; and they had an idea you only had to get your machine, try it a few times, and you had learned it all. I used to tell them I could not tell how long it would take any man to learn it, as one would learn more in two days than another would in two weeks.

Mr. Weston, who was on the corner of Broadway and John-street, told me a very amusing story. A man, he said, came from a neighbouring city to learn to make Daguerreotypes, and after he came in the room and was told what the price would be and the cost of the camera and all that sort of thing, he said, very well, he wanted to take instructions. He was going to stay in New York two weeks. Mr. Weston coated a plate, which was about the plan Professor Landy has shown us here to-night, and he said, "Is that all?" and Mr. Weston said, "Yes, that is all; that is what you do every time." And the man said, "I am not going to pay board here in New York for two weeks for that!—why, I can do that myself!" And so he straightway took his camera and other necessary appliances, and in about four days after that he came back, with fire in his eye, and walked in, holding the camera by the nozzle, and said, "There it is!—it is not worth a damn!" And Mr. Weston said, "What is the matter?" and he said, "It won't take a picture." And Weston coated a plate and put it in the camera, and brought out a picture at once. The man says, "I could not get it." "Of course you could not do it; you only saw me go through the motions two or three times, and you thought you knew it all." He said, "I set it in front of the window where I worked, and about half a mile off there was a hill. Do you suppose that was the matter? Do you suppose that hill made the trouble?" I mention this incident simply to show you what perfect ignorance there was in regard to it.

And then the name of the "Daguerreotype"—as to spelling it, that was almost an impossibility. Some called them "doggytypes," some "daggytypes," some "degytypes," and the vulgar "dogtypes."

And the "dark room" was a place about which a great many people had a very curious and amusing idea. Some would ask, "What do you do in there?" One thought you went in there and did some hocus-pocus and some sleight-of-hand work to develop the picture; and another would say, "You need not be so particular to shut that door; I don't want to steal your trade." We were not so much afraid of the trade as we were of the tools, and in those days you did not see people bring a crowd of persons together to explain to them some new method of development, or a thing of that kind, as you do to-day. Every man that got a hold of an idea kept it to himself, and he would never let another photographer or Daguerreotypist go into his dark room. Every man was the personification of all wisdom.

And then the improvements came so fast! What we learned one day, in two or three days was of no use, for something had been brought out in the meantime that was entirely new, and superseded what we learned a day or two before. The advance has been very rapid in photography.

During my earlier days, in 1816, on a dark day I have often kept people sitting four minutes for a picture. Now, if some of you ladies and gentlemen will take out your watch and time four minutes and tell a man not to wink, you would see what a very difficult thing it was at that time; but the usual sittings were from thirty to forty seconds, and, finally, they were reduced down from ten to twelve; but I have been compelled to take four minutes many a time on a dark day.

Now, as to the Daguerreotype, I want to mention one fact which is not com-

monly known. The Daguerreotype will not fade, and I know what I am talking about when I make that assertion. While it will not fade, it will become tarnished on the surface, but that can be easily cleaned. I have cleaned a great many of them and made them just as perfect as they were the day they were taken, provided some person has not taken a handkerchief and rubbed it out. I remember a case: Only a few years ago a lady came to me with a half-sized picture, and you could not see anything at all upon it. She wanted to know if I could clean it, and I took it and cleaned it, and in about five minutes I brought it to her and showed it to her and she fainted dead away in a moment. It was her husband who had been dead twenty years, and she had not seen the picture in fifteen years. It was so completely covered with a film that there was nothing to be seen, and I brought it up as good as it was originally. As I say, the lady fainted immediately. It was just as if her husband had been brought back from the grave for her to see.

ABRAHAM BOGARDUS.

(To be concluded.)

DAGUERRETYPE.*

THE failure of two such eminent men as Wedgwood and Davy in their attempts to produce light-drawn pictures appears to have discouraged any further experiments of this kind at that time in England. In 1814 M. Niepce, of Chalons-on-the-Saône, turned his attention to the chemical agency of light, his object being to fix the images of the camera obscura, and he appears to have discovered the peculiar property of light, in altering the solubility of many resinous substances. In 1824 M. Daguerre began a series of experiments with the same object in view. The first substances used by him were, according to M. Arago, paper impregnated with a solution of the nitrate or chloride of silver, but his ill-success induced him to abandon them. It is not, however, clear whether any other substances or materials were used by M. Daguerre previously to 1826, when, through a Parisian optician, he became acquainted with M. Niepce. Letters addressed to Niepce received, however, but no responses, and it was not till 1827, when Niepce passed through Paris on his way to England, that he entered into cordial relations with Daguerre. In December of 1827 M. Niepce was in England, and he communicated an account of his experiments to the Royal Society of London, together with several pictures on metal plates in the state of advanced etching; the etching effected by acid subsequent to that part of the process in which light assisted in laying bare portions of the resin-covered plate. These early productions prove that the experimentalist of Chalons was acquainted with the method of making the shadows and lights of his pictures correspond with those of nature, and of rendering his copies impervious to the crasing effects of the solar rays. In a paper, dated December 5, 1829, M. Niepce communicated to M. Daguerre the particulars of the process employed by him, and they entered into an agreement to pursue, for their mutual benefit, the researches which they had respectively begun. A correspondence between M. Niepce and M. Daguerre has been published which sufficiently proves that to the latter the sole merit of the discovery of the process which bears his name is due. In 1831-2 M. Niepce, indeed, regrets that, at the recommendation of M. Daguerre, he had lost so much time in experiments on iodine. "I repeat it, sir," he says; "I do not see that we can hope to derive any advantage from this process more than from any other method which depends upon the use of metallic oxides," &c. In another letter he speaks of a decoction of thapsi (shepherd's purse) fumes of phosphorus, and particularly of sulphur, as acting on silver in the same way as iodine, and that caloric produced the same effect by oxidising the metal; "for from this cause proceeded in all these instances this extreme sensibility to light." We may perceive from these remarks that although M. Niepce may not have been fortunate enough to discover the exquisitely sensitive method of M. Daguerre, he must have submitted to experiment a great variety of substances in different states of combination. The philosopher of Chalons died in July 1833, and a new agreement was entered into between his son, M. Isidore Niepce, and Daguerre.

Five years after the death of Niepce, Daguerre was able to announce that he had overcome all difficulties, and that henceforth nature would depict her own likeness with a pencil of light. In January, 1839, the discovery of M. Daguerre was reported, and specimens shown to the scientific world of Paris. The extreme fidelity, the beautiful gradations of light and shadow, the minuteness and the extraordinary character of these pictured tablets, took all the world by surprise, and Europe and the New World were astonished at the fact that light could be made to delineate on solid bodies delicately beautiful pictures, geometrically true, of those objects which it illuminated.

In the July following, after a bill was passed securing to M. Daguerre a pension for life of six thousand francs, and to M. Isidore Niepce of four thousand francs, with one-half in reversion to their widows, the process by which these pictures were produced was published.

It is to be regretted that—after the French Government had thus liberally purchased the secret of the process of the Daguerreotype, for "the glory of endowing the world of science and art with one of the most surprising discoveries that honour their native land," on the argument that the invention did not admit of being secured by patent, for, as soon as published, all might avail themselves of its advantages—in the face of this, on or about the 15th of July, 1839, a certain foreigner residing in France instructed Mr. Miles Berry, patent agent in London, to petition Her Majesty to grant Her Royal Letters Patent for the exclusive use of the same within these kingdoms. This certainly needs no comment. It was unworthy the liberal spirit which should actuate the follower of science and art. The process was accordingly patented in England in 1839, and in the specification is called "A new and improved method of obtaining the spontaneous reproductions of all the images received in the focus of the camera obscura." Nevertheless, the Daguerreotype process was at the time of its publication very imperfect; and it was destined to undergo important modifications and improvements during the next three or four years.

The news of Daguerre's wonderful discovery soon spread to other countries, and the inventor obtained a rich reward by the sale of apparatus, and by the instruction of hundreds who flocked to Paris to learn the details of the new art. The materials employed by Daguerre in his early experiments, between 1824 and 1829, appear to have been the same as those used by Wedgwood and Davy—the chloride and nitrate of silver spread upon paper; and he did not advance upon, if indeed he equalled, the

* Continued from page 150.

results obtained by the two English chemists. After entering into partnership with Niepce and learning the details of his bitumen process, Daguerre followed for a time in the same track, but further study enabled him to work out improvements and modifications which led him ultimately to a greater success. We know that Niepce sometimes used metal plates coated with silver; moreover, he employed iodine to darken these plates after the picture had been developed. Using these two materials—plates of silver and vapour of iodine—Daguerre found that the iodide of silver formed by exposing silver to the vapour of iodine was sensitive to light. When such "iodized silver plates" were exposed within the camera faint images of bright objects were impressed upon them in the course of two or three hours.

At this stage a happy "accident" occurred which revealed to Daguerre a method by which not only was the time of exposure necessary to secure a good picture greatly reduced, but the distinctness and beauty of the image was much enhanced. It appears that one day Daguerre removed from his camera a plate which, either from the shortness of the exposure or the dullness of the light, showed no sign of an image. He placed this blank plate in a store cupboard, intending to clean the surface and use it again. But what must have been our photographer's surprise when, on taking out this plate the next morning, he found upon its surface a distinct and perfect picture. Another prepared plate was quickly exposed for an equally short time within the camera, and again a sojourn of twenty-four hours within the magic cupboard sufficed to bring out a picture. The next step was to ascertain to which of the numerous chemicals kept within the cupboard this marvellous effect was due. By a process of elimination, it was at last traced to a dish full of mercury. Delighted by this fortunate discovery, Daguerre at once proceeded to place his exposed plates over a dish of warm mercury, when the vapour proceeding from the liquid metal was found to settle upon the iodized silver in exact proportion to the intensity of the light by which each part of the plate had been affected. This was, in fact, a process of development, an invisible or "latent" image being strengthened and thereby made visible. Some such method of "developing" the originally feeble impressions produced upon sensitive plates by a short exposure to light has been found necessary in every photographic process.

Another advance made by the French artist was the discovery of a fixing agent. This was neither more nor less than a strong solution of common salt, in which the plates were soaked after development, and which dissolved and washed away the iodide of silver that had not been acted on by light. But when, almost immediately after the publication of the Daguerreotype process, in 1839, Sir John Herschel drew attention to the superior qualities of hyposulphite of soda as a solvent of the silver salt, Daguerre immediately adopted it for clearing and fixing his exposed plates. This substance, so valuable to every photographer, was discovered by Chancener in 1799 and its power of dissolving the haloid salts of silver had been described by Herschel as early as 1819.

The first Daguerreotypes were so delicate that the merest touch of the finger was sufficient to mar their beauty, and when exposed to the air they rapidly tarnished and deteriorated. This defect was remedied by M. Fizeau, who gilded the image by means of a mixture of chloride of gold and hyposulphite of soda. This solution was poured over the silver plate, which was then heated until the liquid evaporated, leaving a thin coating of gold upon the picture, which was thereby more distinct as well as more permanent.

Another great improvement was introduced by Mr. Goddard, a London science lecturer, in 1840. He exposed the iodized silver plate to the action of bromine vapour, thereby forming a bromide of silver upon the plate in addition to iodide of silver. In 1841 M. Claudet used chlorine vapour in a like manner. Plates prepared by either of these methods were found to be far more sensitive to light than those which had been simply iodized. In fact, the time required to produce a picture in the camera was thereby reduced to from one to five minutes, or, with a very good light, to less than one minute. As the three elements referred to were only discovered—chlorine in 1774, iodine in 1811, and bromine in 1826, we see that photography was hardly possible before the present century.

After the improvements of Goddard and Claudet, which were quickly adopted by Daguerre, the production of portraits by the Daguerreotype process became comparatively easy. In the first attempts at portraiture, which appear to have been made in America by Draper and Morse in 1839, the sitter's face was covered with white powder, the eyes were closed, and the exposure, lasting for perhaps half an hour, was made in bright sunshine. To lessen the glare of light, which painfully affected the sitter, Draper caused the sunlight to pass through a large glass tank containing a clear blue liquid—ammonia and sulphate of copper—before falling upon the sitter, thus filtering out most of the heat rays, which could well be spared, as they possess little or no actinic value.

In 1840 Beard and Claudet opened photographic studios in London. Davidson followed suit in Edinburgh, and George Shaw in New-street, Birmingham, and soon Daguerreotype became a trade. For landscapes, &c., the Daguerreotype process was, however, but seldom employed, though we read of a fine instantaneous picture of New York Harbour being secured by its aid.

The expense of the plates, which were usually of copper, plated with silver, was a serious objection to the Daguerreotype process. As late as 1854 we find the price of Daguerreotypes in England was two and a half guineas each for the quarter-plate size (4½ x 3½), and four guineas each for half-plate size. The cleaning and polishing of the silver surfaces on which the picture was to be produced was a most troublesome task, necessitating great care and a vast amount of labour in the production of the "black polish" which was necessary. It must also be remembered that there was practically no power of multiplying a Daguerreotype, a fact due to the opacity of the silver plate. It is true that Grove (now Sir W. R. Grove, one of Her Majesty's justices) devised a method of etching Daguerreotypes with acid so that they could be used in a printing press, but, practically, this method was a failure.

The Daguerreotype held sway for about ten years only—from 1839 to 1851. It was more popular in America than in England; indeed, in England specimens of the art are now quite rare. With all its faults, it was an immense advance on anything previously known, and entitled Daguerre to rank with the leading inventors of the nineteenth century. Daguerre died in 1851, aged sixty-three. In 1853, a bust of this ardent worker was unveiled at Cornhill, funds being contributed by photographers of all civilized nations.

Viewing his whole career, Daguerre must be considered as a fortunate man. Not only did he reap much honour and material benefit from his discovery, but he lived to see photography rise to an important place amongst the arts and sciences.

I will now give you Daguerre's original process of making his pictures.

The pictures of the Daguerreotypes are executed upon thin sheets of silver, plated on

copper. Although the copper serves principally to support the silver foil, the combination of the two metals appears to tend to the perfection of the effect. It is essential that the silver be very pure. The thickness of the copper should be sufficient to maintain perfect flatness and a smooth surface, so that the images may not be distorted by any warping or unevenness. The process is divided into five operations. The first consists in cleaning and polishing the plate to fit it for receiving the sensitive coating on which light forms the picture. The second is the formation of the sensitive ioduret of silver over the face of the tablet. The third is the adjusting of the plate in the camera obscura for the purpose of receiving the impression. The fourth is the bringing out of the photographic picture, which is invisible when the plate is taken from the camera. The fifth and last operation is to remove the sensitive coating, and thus prevent that susceptibility of change under luminous influence which would otherwise exist and quickly destroy the picture.

(To be continued.)

W. THOMAS HORTON.

THE PHOTOGRAPHIC EXHIBITION, CALCUTTA.

THE following are the list of prizes awarded by Colonel Waterhouse and Mr. W. H. Jobbins, the Judges nominated by the Photographic Society to decide on the merits of the different exhibits:—

Class A. (open to all exhibitors).—No. 1, gold medal, to Messrs. Johnston & Hoffman, for portrait of Mrs. Ian Hamilton. No. 2, special medal, to Lalla Deen Doyal, for a series of six photographs of places—such as the Ridge Simla, the Benares Giants, the Ellora Caves, &c. No. 3, extra silver medal, to P. Klier, of Rangoon, for *Patience*, and *Papa is Coming*.

Class B. (open to all amateur exhibitors).—No. 1, silver medal, to Mr. E. M. Showers, for *Match between "Honor Bright" and "Landshark,"* with a hand camera. No. 2, silver medal, to Mr. A. Norman, for at Shanklin, Isle of Wight, the Thames at Wargrave, Pangbourne, and Henley. No. 3, silver medal, to Mr. J. J. Meade, for his series of photomicrographs. No. 4, bronze medal, to Mr. T. Miller, for the four roadside views near Calcutta.

Class C.—This silver medal has not been awarded.

Class D. (open to members of the Photographic Society only).—No. 1, silver medal, to Lieutenant Dick, for enlargements and a series of views in Cashmere. No. 2, silver medal, to H. H. the Bara Thakur of Tipperah, for the excellence of his series of photographs as artistic pictures and as platinum prints. No. 3, bronze medal, to Captain Wedderburn, a series of views in the Eden and Zoological Gardens, Belvedere, also shipping elephants for the Chittagong Expedition.

The Judges also desire to honourably mention the photographs by Messrs. J. S. Gladstone, A. Fleming, Geo. Ewing, and A. E. Caddy; also Mr. J. C. White's portrait of the Maharani of Sikkim.

Our Editorial Table.

WOOD'S WASHER FOR PRINTS AND PLATES.

WE have received from Mr. James Wood, of Liverpool, one of the print and plate washers bearing his name. It is claimed that the hypo can be removed from a print in thirty minutes, and from a plate in fifteen minutes.

The washer is so constructed that there are no corners into which the prints can get jammed and creased, but they are kept always on the move.

For the convenience of holding the plates there is an adjustable rack

which is set into the water. The rack is adjustable for several different sizes.

The whole apparatus is substantially made, and on account of its utility will doubtless become widely known. Its form is shown in the above cut.

PATENT COMPLETED.

INSTANTANEOUS SHUTTER FOR PHOTOGRAPHIC APPARATUS.

No. 12,707. CHARLES BOUCKAERT, Brussels, Belgium.—*March 3, 1888.*

THE apparatus known as instantaneous shutters, employed in photography up to the present, have the serious inconvenience of being too large or not sufficiently compact to enable it to be placed in the interior of the camera.

The object of my invention is to remedy this fault, as my apparatus may be placed inside any camera without interfering with the action. All the movements, either for setting or for relaxing the spring so as to increase or decrease the rate of motion of the instantaneous shutter, are effected from the outside of the apparatus.

One of the advantages of my instantaneous shutter is that it can be placed either inside or outside the camera as desired.

Another essential advantage is that the shutter is put into action without uncovering the object glass or lens.

The apparatus having been once fixed to the camera does not require to be opened unless it is necessary to change the diaphragm.

The apparatus is composed of a plate fixed to the camera by means of holes, and on which all the mechanism is mounted. A lever working on an axis is actuated by a spiral or other spring attached eccentrically on a movable rod by which it can be rendered stronger or weaker by turning the rod to the right or to the left.

This lever carries at one end a blade spring terminated by a tappet, which takes under a pivot on the shutter to act upon it when moved.

Another lever has a spring and two detents for throwing the first lever into and out of gear. A third lever is provided with a fork, in which works the pivot, and which serves to move the instantaneous shutter. A small pin or tappet fixed to the first lever, strikes against the third lever to cause the return of the shutter.

The movement of the first lever may be retarded by arranging a small rack actuating a pinion mounted on the same axis with a small flyer.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

MARCH 12.—Mr. James Glaisher, F.R.S., President, occupied the chair.

THE PRESIDENT announced that Captain A. M. Mantell, R.E., had been appointed honorary secretary to the Society, and that Mr. Brownrigg had been appointed a member of the Council.

Mr. F. W. Hindley and Miss Mildred were elected members of the Society.

THE PRESIDENT read a letter from the Society of the Photographic Amateurs of New York offering its congratulations to the Photographic Society of Great Britain on the occasion of the close of the first and beginning of the second half century of photography. He remarked that it was a pleasing communication from New York.

MR. FRIESE GREENE opened the discussion on Mr. Swan's paper on quinol, by saying that if the quinol developer were mixed a quarter of an hour before use it worked better than if employed at once, and gave better pictures; the operator could go on developing plates for four or five hours in the same solution. He found the negatives to be superior to those produced by other developers. If the plates were soaked in sulphite of soda for half an hour before applying the quinol developer the time of exposure could be reduced by one half.

MR. S. G. B. WOLLASTON had developed a large number of stripping film negatives with quinol and compared them with his best pyro developed negatives; he then found that quinol had distinctly given the best results.

MR. NOWLAN exhibited negatives which he had developed six years ago with quinol and washing soda, with nothing else.

MR. W. COBB asked if Mr. Wollaston had formed his conclusion from the negatives or prints taken from them.

MR. GEORGE DAVISON asked in what respect Mr. Wollaston's quinol developed negatives were better than the others.

MR. WOLLASTON never judged the character of a negative until he had taken a print from it in platinum as well as in silver, the former being the more trying test of the two. He found that with quinol the exposure of the plate could be lessened, and that the films would strip with water at half the usual temperature employed.

MR. T. SERASTIAN DAVIS said that quinol did not stain the surfaces of the negatives, and that it was especially useful for transparencies. He exhibited some quinol developed lantern slides in which portions of the print were as clear as the margins which had not been exposed to light; he also exhibited some pyro developed slides not so clear in this respect. He wished to know how Mr. Swan proceeded with quinol when he was not sure of the amount of exposure of the plate. He (Mr. Davis) then exhibited three pictures, one of which had had five seconds' exposure, another seven and a half seconds, and the third ten seconds. He had obtained good results with all these by applying the alkaline solution first and adding to it quinol and sodium sulphite solution little by little as it seemed to be required; the margins of all three plates were absolutely transparent.

MR. DAVISON thought that most of the published formulæ recommended too small a proportion of quinol, and that a larger quantity thereof increased rapidly; he had also found that quinol did not do so well as pyro for under-exposed plates, at least that was his experience after trying it on and off for two years. He doubted if the printing quality of the quinol developed negatives equalled their visual appearance, and he had heard a rumour that Mr. Swan's operator, Mr. Green, liked pyro best. Quinol was good for lantern slides and for paper development. As to staining effect Mr. Davis's experiments had been tried with a larger proportion of pyro than of quinol, which was not fair to the pyro; in comparative experiments he thought that six grains of quinol should be tried against four grains of pyro.

MR. LEON WARNERKE had seen results in which lowering the proportion of sulphite had increased the intensity of the negatives. In trying his process of developing silver prints like carbon tissue, he had found that quinol made the film quite insoluble in hot water, so his experience did not agree with that of Mr. Wollaston. He was favourably impressed with the quinol developer and had used it for many years, especially upon chloride films.

MR. GEORGE SCANNELL had tried quinol five or six years ago, and then given it up. Recently he had tried it again, making comparative experiments in relation to latitude of exposure, and would hand round his results in the shape of negatives and the proofs taken from them; his conclusion was that the old pyro and meta-bisulphite of potash developer gave the best results, so he had gone back to it.

MR. A. MACKIE said that Mr. Swan had stated that a largish proportion of meta-bisulphite of potash was bad for the quinol developer; had he tried an extra amount of alkali with it to overcome the effect of the excess of sulphurous acid? With collodio-bromide plates quinol answered admirably, and gave a good colour.

MR. W. E. DEBENHAM agreed with Mr. Mackie, and thought that Mr. Montefiore's excellent negatives had proved the point.

MR. W. ENGLAND'S experience with quinol was small, but the results had been promising; it would bring out under-exposed plates which pyro would fog in the forcing; much depended upon the plates used. The time of development with quinol was seven or ten times longer.

MR. DAVIS said that in his experiments he had used chloro-bromide gelatine plates, and developed with Hopkin & Williams' quinol, which he understood was prepared from the bark and not from the benzine compounds.

MR. J. HUBERT had found that with Wratten's plates the time of development was the same as with pyro and ammonia, when the quinol developer was prepared by Swan's formula; he had also found that the range of half tone was not quite so good as with pyro. His negatives were developed in from two to three minutes.

MR. CONNELL had helped Mr. Hubert in his experiments, and thought quinol to have been a little slower than pyro therein; in the earlier experiments the quinol developer was slightly the warmer of the two, and then the times of development were about equal.

MR. HUBERT added that in the later experiments the developers were applied at the same temperature.

MR. A. COWAN thought that it had been proved that quinol was nearly as good as pyro. Sometimes it gave a yellow stain which was deeper the larger the proportion of sulphite; perhaps that result might have been due to peculiarities in his sample of quinol.

MR. J. W. SWAN said that in the absence of sulphite of soda, or of some equivalent therefore, considerable stain resulted; he had recommended the minimum proportion of sulphite to prevent stain. In the formula he had given, the proportions were such as to make the quinol developer work as

rapidly as a pyro developer, which would bring out the image in two and a quarter minutes. Quinol is not slow when caustic potash is used as the alkali. He doubted if much could be claimed for quinol in relation to under exposed plates, although pyro would give a little more fog. As to the tanning action, he thought that the difference in the results of Mr. Warnerke and Mr. Wollaston, might be due to difference of plates; his own experience agreed with that of Mr. Wollaston. He thought that Mr. Scamell's results should be carefully considered; they proved that as yet we are all inexperienced in the use of the quinol developer. He had not said that meta-bisulphite of potash could not be used with the quinol developer, but that an excess of it was dangerous, and would almost destroy the activity of the solution. As regards prints from negatives to prove their quality, Mr. Wollaston had done it, but probably experienced photographers were not generally deceived as to the printing qualities of their negatives before they had tried them, unless the colours were such as to be misleading; quinol negatives much resembled the old wet plate collodion negatives. The fact that the action of a good quinol developer is limited to the parts on which light has acted, is exceedingly useful for transparencies, and above all for negatives intended for use in photo-mechanical processes. There is much yet to be done in experimenting with quinol, to ascertain how far and in what method it can be made to compensate for under and over exposure. Sulphite of soda with quinol tends to make the image weaker.

Mr. DEBENHAM asked if adding more alkali would not overcome the retarding influence of excess of meta-bisulphite of potash.

Mr. SWAN had not tried it. He had been much pleased with the interest his paper had excited among the members of the Society.

Mr. LEBLIS MONTEFIORE had found no advantage in adding a bromide to the quinol developer; he thought it but complicated matters as an unnecessary introduction.

Mr. ARNOLD SPILLER had experimented with the quinol developer years ago, and found that it slightly shrank the film wherever the image was formed, but in his experience the tanning effect was not strong enough for practical purposes; pyro acted more strongly in this respect.

Mr. SWAN had tried an experiment on the point that day, and contrary to the experience of Mr. Spiller, the image was raised where the light had fallen; in hot water the image came off the plate, and the rest of the film dissolved.

Mr. SPICER had used no sulphite in the developer in his experiments.

The PRESIDENT read a letter from the Rev. Mr. Sutton, British chaplain at Luxor, in Upper Egypt, saying that he had been photographing the interiors of tombs, using Abney's and Monckhoven's plates, and found the latter the better of the two; he had also found that the quinol developer gave the best results in that climate. The speaker then announced that from March 18 to March 26, there will be an exhibition of Alpine and Caucasian photographic views taken by the late Mr. W. F. Donkin; the exhibition will be open from ten a.m. to six p.m. at the Gainsborough Gallery, 25, Old Bond-street, London. Some members of the Council, he added, wished to gather the opinion of the members upon the question of "medals or no medals" at the next exhibition of the Society, and this subject would be considered at the next meeting.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

MARCH 7.—Mr. A. Mackie presided.

A question in the box asked the best preservative of pyro in solution.

Mr. J. B. B. WELLINGTON stated that sulphites were good, and any acid would do; it was entirely a matter of taste.

Mr. A. HADDON said that there was a serious objection to nitric acid or any of the class of acids which would yield oxygen to the pyro; sulphite of soda was objectionable when alkaline, and if made acid with citric acid would contain some of the strong restrainer, citrate of soda. Sulphurous acid, being an absorbent of oxygen, was one of the best to preserve pyro.

Mr. WELLINGTON remarked that when a plate was predisposed to green fog sulphite of soda had a tendency to increase it.

Question: "Does a preservative act as a restrainer?"

Mr. HADDON replied that it all depended upon the preservative used.

Question: "Should you focus again after stopping down?"

Mr. HADDON replied that when any lens gave spherical aberration focusing should be repeated after stopping down.

Mr. EDGAR CLIFTON said that old periscopic lenses depended entirely upon stopping down for achromaticity.

Question: "What is the best way of transferring engravings in printing ink from paper to glass plates for lantern slides?"

Mr. CLIFTON replied that a compound for doing it was on sale in the market; he believed that it contained alkali and soap. Old books recommend sticking the print to the glass with copal varnish, then rubbing away the paper, and afterwards varnishing again; but this plan results in a kind of ground-glass effect. A piece of sheet gelatine may be laid on the picture, the lines then traced on the gelatine with the point of a needle so as to scratch its upper surface, and red chalk or Venetian red rubbed into the cracks with the fingers; the lines will then show black on the screen.

The HON. SECRETARY said that the simplest way was to photograph the print.

Mr. HADDON suggested tracing the engraving on ground glass with a pencil and then varnishing the glass. At the Edinburgh Photographic Society a member had exhibited a Wray's lens shutter and stated that it would give exposures of from two seconds to one-fourth-hundredth of a second. Had any one present had experience with a shutter which would do that? He should like to know by what method the speed had been measured.

Mr. A. COWAN suggested that Mr. Wray had better be invited to kindly attend a meeting of the Association and to explain.

Mr. CLIFTON thought a committee should be appointed to test the speed of shutters and to fix standards.

Mr. WALTERS asked the best way to copy old oil paintings so as to get pucky negatives.

Mr. W. H. PRESTWICH suggested the use of orthochromatic plates.

Mr. COWAN suggested putting the painting in direct sunlight, so that the

light falls on it at an angle of forty-five degrees, and no glare is reflected into the lens, the optical axis of which should be perpendicular to the plane of the face of the painting.

The HON. SECRETARY said that such copying was often not easy work, and that some paintings could not be copied well with orthochromatic plates.

Mr. CLIFTON suggested rubbing the face of the painting over with half a potato, to give it an even sort of gloss.

Question: "Is pyro better than quinol?"

Mr. WELLINGTON preferred pyro because he saw no advantage in quinol.

Mr. CLIFTON thought that it would supersede ferrous oxalate, especially as it needed no subsequent acid bath in paper work.

Mr. J. J. BRIGNSHAW asked what latitude quinol gave.

Mr. HADDON replied that Mr. Montefiore had said that in one dish of it under-exposed and over-exposed negatives could be developed.

Mr. CLIFTON, when trying quinol one day, thought it would not bring out the picture; he left the plate for three quarters of an hour, and when he returned was surprised to find an excellent negative developed upon it. The quinol developer, when properly made, seems never to fog or stain.

The CHAIRMAN read some extracts from Mr. J. W. Swan's recent memoir on the subject.

Question: "Is hypo a reducer of gelatine negatives?"

Mr. C. H. COOKE had found that by three or four days' immersion the plate was reduced nearly to clear glass.

Mr. CLIFTON said that during the first twelve hours hypo did not attack the image much, but afterwards it made headway. Hypo in conjunction with atmospheric influence was a powerful reducer, as he had accidentally found after laying aside an unwashed plate; where part of the surface had been protected from the atmosphere by contact with another piece of glass the image had not been reduced.

Mr. WELLINGTON had known a bromide print left in hypo for four or five days to change from red to slaty blue.

Mr. F. A. BRIDGE had had the opposite experience; the colour changed to a very nice brown. He used the same hypo for negatives, paper prints, and all purposes without finding any disadvantage.

Mr. PRESTWICH used alum in a hypo bath neutralised with carbonate of soda.

Mr. HADDON observed that if he had added some sulphate and sulphite of soda to the fixing bath he would have obtained the same solution and been saved the trouble of filtering.

Mr. COOKE had tried alum as stated, and in his hands it gave abominable stains.

Mr. WELLINGTON gave a formula for solutions to be used in quinol development, which will be found on page 179.

CAMERA CLUB.

MARCH 7.—Mr. W. Asbury Greave in the chair.

Mr. W. ADCOCK read a paper entitled *Alum*.

Previous to the lecture the HON. SECRETARY drew attention to a fine set of old photographs, presented by Mr. H. P. Robinson, which it was to be hoped would form the nucleus of a historical collection of prints to be organized parallel with the growing Club library.

The lecturer, in his address, emphasised the need for invention in photographic work. Pot-boilers should be left, and new and original ideas worked out. Let one really fine picture satisfy as a year's work. Size he thought essential, and urged the production of large direct heads. Members of societies might combine to obtain large expensive apparatus, and suitable studio convenience for important work.

In the discussion Messrs. H. P. Robinson, Graham Balfour, E. Ferrero, G. Davison, S. B. Webber, and J. Gale made remarks.

On Thursday, March 21, a paper on *Exposure* will be read by Mr. H. C. Bond, M.A. Meeting at eight p.m.

WEST LONDON PHOTOGRAPHIC SOCIETY.

MARCH 8.—Mr. W. England (President) in the chair.

Mr. G. F. BLACKMORE, in describing a new method of toning lantern slides, said:—

It was well known that the silver image of a transparency or negative might be modified in colour by certain toning processes, and also by varying the exposure and the development. He believed, however, that the process he was about to introduce to their notice possessed novel features and appeared to open a wide field of investigation. Working by his system it was possible to make a transparency agree in colour with the nature of the subject, and a greater variety of colour could be obtained with greater certainty than was possible with any system of development. His early experiments were of a haphazard character. Observing the changes of colour which prints toned by the sulphocyanide bath underwent, the idea occurred to him that it might be possible to obtain similar effects with lantern slides. His first experiment consisted in bleaching an ordinary bromide transparency with mercury and afterwards placing it with some aristotype prints in the sulphocyanide toning bath; these slides, after protracted immersion (some six hours), ultimately toned to a purple colour. On the toning bath being raised to about a tepid temperature the time was reduced to about an hour and a half—still too long for practical purposes. The proportion of gold was then increased, with the result that the toning proceeded more rapidly. He found from three to four grains of gold to the ten ounces of solution to be about the limit; a larger proportion of gold caused a tendency to precipitation. With this strength toning took place in from ten to fifteen minutes, the colours obtained ranging from greenish-blue to deep purple. Of all the methods tried the most promising seemed to be to soak the plate, after bleaching with mercury, in a weak solution of gold (one grain to the ounce of water) previous to placing it in the sulphocyanide bath. A great range of colour was obtainable by varying the time of immersion in the gold solution. The bleached image could be toned in the gold solution alone, but, in order to secure permanency, the tone in this case should be very complete. Toning in the aqueous solution of gold yielded greenish-blue tones, which were very suitable for moonlight effects. The colour could be modified to a steely blue by a slight sub-

sequent immersion in the sulphocyanide bath, but to obtain this effect the preliminary gold toning must be thorough, otherwise the resulting colour would be a deep purple. Other bleaching agents were experimented with. Slides bleached with cupric chloride resisted all attempts at toning, others bleached with iodide of mercury proved equally intractable. The borax bath was also used, but, after several hours' treatment, was found to have no effect upon the image. Other well-known toning baths were not tried, thus a large field of experiment was open to those who might feel interested in the matter. In summing up, Mr. Blackmore said that to obtain an extensive range of colours by toning it was essential, first, that the image should be bleached with bichloride of mercury prior to toning. Second, that with the sulphocyanide bath containing one to two grains of gold to the ounce of solution, and used cold, a range of tones varying from steel blue to a delicate pink might be obtained; further, that by keeping the bath above a tepid temperature the result would be achieved in a shorter time. Third, increasing the proportion of gold would cause the toning to be more uniform and warmer in colour. Fourth, tones varying from greenish-blue to pink and magenta could readily be obtained by giving the plate a preliminary soaking in a plain gold solution followed by immersion in the sulphocyanide bath, the plate being washed between each operation. Fifth, care should be taken to select slides with thin images, as considerable intensification as well as toning occurred. Many points remained to be cleared up, such as the results to be obtained from the bath being in an acid, alkaline, or neutral condition; the effect of dispensing with or adding a larger proportion of hypo to the sulphocyanide bath; also of increasing or diminishing the amount of ammonium salt—all these suggestions opened up a wide field for investigation.

The PRESIDENT said Mr. Blackmore's paper had disclosed a very promising method of toning slides, and he hoped members would take the matter up with a view, if possible, of further developing the process.

Mr. HODGES believed Mr. Blackmore's process to be a new departure in toning bromide transparencies, although toning collodion slides with gold and platinum was well known, but in bleaching the image preparatory to toning with gold Mr. Blackmore appeared to have struck out a new line. The process, however, would require careful working in order to avoid too great a deposit and consequent blocking of the lights.

Mr. WHITING had found that by varying the exposure and modifying the development he could get almost any desired colour on commercial plates, therefore he did not see the necessity of resorting to any toning process.

Mr. J. S. DESIRÉ ENGLAND said warm tones could be produced easily on chloride plates with a suitable exposure and development.

Mr. HARBREAVES had found it impossible to bleach Thomas's lantern plates with bichloride of mercury without first thoroughly soaking in water.

Mr. BLACKMORE, in reply, said he believed that the silver image could be bleached, no matter what condition the film was in, although at times both bleaching and toning operations were somewhat erratic. It was desirable to soak the plates in a solution of chrome alum before toning, as the prolonged treatment tended to make the film rotten. If the cold tones were desired the toning should be proceeded with immediately after development, and before allowing the film to dry, but if the warm tones were sought the result would be more readily obtained by first allowing the plate to dry.

Two hundred slides were exhibited by means of the lantern.

Mr. HODGES handed round a negative and a transparency on Beechly plates prepared some twelve years ago. They were produced by a friend of his, Mr. Paul, who, in turning over some old apparatus, had come across a dark slide with the unexposed plates in it. After the milkew with which they were covered had been removed, they were exposed, and, as the result proved, were found to be still sensitive to the action of light.

HOLBORN CAMERA CLUB.

At the special general meeting, held on the 8th instant, an address was delivered by the PRESIDENT (Mr. W. Rice), detailing the progress of the Club, and inviting all interested in the proceedings to attend any of the future meetings, which will be held at the headquarters of the Club, 100, High Holborn, every Friday from seven to eleven p.m.

The following gentlemen were elected members:—Messrs. Louis Smeed, A. J. Raymont, H. Beckford, G. F. Asterooth, C. Irving (Platinotype Company), N. Dukas, Albert Bell, H. C. Gay, F. W. Gay, and Samuel Withlers.

Special class for learners the third Friday in each month; no fees; open to all.

Annual general meeting, April 5.

SHAFTESBURY PHOTOGRAPHIC SOCIETY.

MARCH 8.—Mr. Tollett in the chair.

Mr. BAKER read a paper entitled *Trips round London with my Camera*. Mr. Baker showed views of Windsor, Kingsbury, Boxhill, Dorking, and a group of pictures of Volunteers at Aldershot.

Messrs. Wills, Noel, Tollett, and Samora took part in the ensuing discussion. In consequence of an inquiry having been made at the previous meeting as to the most desirable camera for a lady to use, Mr. Wills exhibited the Aurora hand camera, concealing within a space of 10×4 twelve quarter-plates for exposure in a quarter-plate bellows camera, and weighing in all from four to five pounds. This was considered to be one of the most compact cameras ever brought before the notice of those present.

Two new members were elected.

Next Friday, the 15th instant, at a quarter-past eight, Mr. J. B. Rintonl will give a lecture, *In and Round London*, illustrated by about one hundred photographs shown as dissolving views. Visitors cordially invited.

CROYDON MICROSCOPICAL AND NATURAL HISTORY CLUB.

PHOTOGRAPHIC SECTION.

MARCH 1.—Mr. A. H. Allen in the chair.

Mr. WILLIAM BROOKS gave a demonstration of the collodio-bromide process for transparencies, lantern slides, &c. The lecturer described the operations involved, and protested against the prejudice which exists concerning the pro-

cess owing to its supposed difficulties. He cleaned and coated a plate in the full light, and when the gas was turned down developed a splendid lantern slide from one previously exposed. The subsequent operations of fixing, toning, reducing, and intensifying were shown in full gaslight.

The CHAIRMAN complimented Mr. Brooks on behalf of the members on the success of his experiments.

LEWES PHOTOGRAPHIC SOCIETY.

MARCH 5.—The President in the chair.

Messrs. E. J. Baker and J. J. Holloway were elected members of the Society. It was decided to hold an exhibition of members' work in the autumn, the details to be arranged by the Committee.

Mr. G. FOXALL read a paper on *Carbon Printing*, and went through the process by demonstration, and passed round for the inspection of the members the prints which he had developed and which had been exposed previous to the evening.

Mr. C. A. WELLS showed three carbon prints, and explained that they had been produced by himself some years ago, when the process was not so simple in manipulation as at the present time.

Some fine prints and enlargements, sent on loan by the Autotype Company, were exhibited.

A home-made detective camera was shown by Mr. G. E. Constable, with specimens of negatives taken with it; also other negatives and prints.

At the next meeting, to be held on April 2, Mr. J. Tunks will read a paper on *Hints to Beginners*.

BOLTON PHOTOGRAPHIC SOCIETY.

MARCH 7.—Mr. Walter Knowles in the chair.

Dr. Johnson exhibited the monthly *Album of the Argosy Postal Club*.

Mr. RICHARD LEIGH exhibited negatives taken on celluloid supports instead of glass; they were manufactured by Messrs. Allen & Rowley, of Boston, U.S.A. The negatives were greatly admired for their lightness, and Mr. Leigh stated that they were quite as easy to work as glass.

Mr. WALTER STATION exhibited an album of views taken whilst on tour in North Wales, the prints all being on Obernetter paper. He remarked that there was a print in the album from every negative he exposed on that tour.

Mr. Thomas Parkinson showed a variety of apparatus manufactured by C. Vevers, of Leeds, and Mr. A. Harper a number of prints.

COVENTRY AND MIDLAND PHOTOGRAPHIC SOCIETY.

MONTHLY meeting, March 6.—A large number of members and their friends were present to witness the lantern exhibition promoted by the Lantern Committee of the Society.

About two hundred and fifty slides, the work of members, were shown by the oxyhydrogen light, the lantern being efficiently worked by Mr. F. W. Dew. Mr. Ambrose contributed some views and very successful copies of engravings; Messrs. Owen and Orton, some local and other views; Mr. Sturmev, about one hundred slides of cycling subjects, views, and hand-camera pictures; and Mr. Dew, instantaneous studies of animals and children, views in the neighbourhood and North Wales. With a good light, plenty of slides, and an appreciative audience, the exhibition was in every way a success, and was thoroughly enjoyed by all present.

A meeting for the transaction of business was held at the close, and it was settled that at the next meeting there should be an exhibition of members' apparatus, and, time permitting, some flash light portraiture.

GLOUCESTERSHIRE PHOTOGRAPHIC SOCIETY.

MARCH 11.—The President (G. Embrey, F.C.S.) in the chair.

Eight new members were elected:—Rev. Mowbray Trotter, Messrs. Clinch, Gillar, Hancock, Hughes, Johnson, Friday, and Round.

Mr. W. B. WOOD read a paper on *Picturesqueness in Photography*, illustrated by a number of lantern slides.

The HON. SECRETARY announced that the Society's new rooms were being furnished and would soon be ready for occupation.

DARLINGTON PHOTOGRAPHIC SOCIETY.

MARCH 11.—Mr. G. Newby Watson in the chair.

Messrs. E. V. Clark, W. Otley, W. R. L. Forrest, and Drs. Smith and Anderson were elected members.

Demonstrations of James's magnesium flash light were given by Mr. R. A. LUCK.

The PRESIDENT followed, substituting guncotton in the place of magnesium powder, but the former light was found to be the more actinic of the two.

Several of the members availed themselves of the opportunity to expose some plates.

At the next meeting, to be held on April 8, Mr. W. F. K. Stock will read a paper on *Hydroquinone as a Developer for Dry Plates*.

DEVON AND CORNWALL CAMERA CLUB.

MARCH 5.—Mr. Robert Murray in the chair.

The HON. SECRETARY requested those who exposed plates at the last meeting, when a series of tableaux were photographed by magnesium flash lights, to produce either the negatives or prints. The results, as a whole, were considered satisfactory and very encouraging.

Mr. GAGE TWEEDY then gave a demonstration on *Development without Washing*. He pointed out that occasionally a photographer was so situated that it was difficult, or even impossible, to obtain a sufficient supply of fresh water for the use of the ordinary methods of development; notably on board

ship; he, therefore, wished to bring before them a remedy for this inconvenience. He produced two half-plates—Edwards's isochromatic—which had been exposed that afternoon on a figure-subject in a fairly lighted room, the one four seconds the other six seconds, with a rapid rectilinear lens working at $f/8$. These he developed in a solution of pyro, two-thirds of a grain to the ounce, preserved by meta-bisulphite of potash and carbonate of potash twenty grains, a proportion which he strongly recommended at this time of the year. When the high lights showed clearly at the back of the negative he immersed it, without washing, in the following solution, which had been previously prepared:—Two ounces of alum was dissolved in twenty ounces of water, making what might be termed a half-saturated solution, to this was added four ounces of hyposulphite of soda. This should be allowed to stand about two days, during which time a white precipitate would be thrown down; the remaining clear liquid being that to be used as shown. The solution would keep good a couple of months, and probably longer. As soon as fixed the plate was removed from the dish, carefully wiped with a cloth, and put away, to be washed at a convenient time. One curious result of the process was the extreme hardness of the film; it was difficult to scratch it with a finger nail. This hardness was of course a great advantage, as it was not so liable to damage.

A discussion followed. Mr. Tweedy's demonstration was considered very valuable, especially with certain kinds of plates given to frilling.

The next meeting will be on the 29th instant, when Dr. Aldridge will read a paper entitled *Picture Making, not merely Taking Photographs*.

CARDIFF AMATEUR PHOTOGRAPHIC SOCIETY.

MARCH 6.—Mr. T. Mansel Franken in the chair.

After the ordinary business had been transacted, Mr. A. W. ALLEN delivered a lecture on *Photography as an Art*. The extensive practice of amateur photography as an art to many pursuits pertaining to art receives the full consideration of the lecturer, and, with the aid of the pencil he graphically described how to make an artistic picture photographically.

An illustration was also given by the power of the new magnesium flash light in producing instantaneous portraits at night, two excellent negatives of the President being secured and developed.

The lecture given by Mr. Storrie recently to the members privately on his discoveries at Llantwit-Major will be repeated shortly for the benefit of the general public and under the auspices of the Society.

On March 20, Mr. W. Windsor will demonstrate on *The Lantern and How to Work It*.

BRECHIN PHOTOGRAPHIC ASSOCIATION.

MARCH 6.—Dr. Anderson, Vice-President, in the chair.

It was arranged to have a field half day on a Wednesday or Saturday towards the end of April.

Mr. A. Brown was elected a member of the Council in room of Mr. D. Holgeton, who has left for South Africa.

Thereafter Mr. J. C. MIDDLETON read a paper, *Suggestions on Picture Making*. The Secretary exhibited some slides on Mason plates developed with the pyro developer recommended for these, showing how various shades of brown could be obtained.

Some questions which had been put in the hat and drawn for at a previous meeting then received attention.

At a meeting of the Council the Rev. T. L. Ritchie was elected an honorary member of the Association.

SOCIETY OF AMATEUR PHOTOGRAPHERS OF NEW YORK.

ONE of the most enjoyable exhibitions, representing the work of a single member, was given at the rooms of the Society, 122 West Thirty-sixth street, on Wednesday evening, February 29, 1889. The subject was *A Trip with a Detective Camera through Norway and France*, the negatives and slides on dry plates being the work of Mr. Richard H. Lawrence. The exhibition comprised one hundred and twenty slides of interesting subjects. The pictures, with the exception of a few interiors and some others, were made instantaneously. Most of the slides were made on dry plates and were developed with pyro, hydroquinone, or iron.

Correspondence

Our Correspondents should never write on both sides of the paper.

MEETING OF THE PHOTOGRAPHIC SOCIETY OF FRANCE.—LETTERS RECEIVED FROM FOREIGN SOCIETIES ON THE OCCASION OF THE FIFTIETH ANNIVERSARY OF THE DISCOVERY OF PHOTOGRAPHY.—A PRINT IN NATURAL COLOURS.—MEDALS AWARDED.—LATENT IMAGE DEVELOPED AFTER TWO AND A HALF YEARS.—A NOVELTY IN PHOTOGRAPHY.—AN APPARATUS FOR EXPERIMENTING ON LENSES.—EXHIBITION OF PLATINUM PROOFS.—A HAND CAMERA.—A NEW APPARATUS.—A NOTE FROM M. GAUTHIER VILLARS.—MY TOUR TO THE SOUTH OF FRANCE.—CONDÉSCENSION OF THE PRINCE OF WALES.

THE Photographic Society of France held its monthly meeting on Friday evening, the 1st instant, M. DAVANNE in the chair.

On the occasion of the fiftieth anniversary of the discovery of photography, the Photographic Society of France received several complimentary letters from foreign societies (Christiania, Copenhagen, Vienna, Boston, &c.), at the same time expressing their desire to have some relic of Niepce or Daguerre.

M. Chardon presented the Society with a print obtained in natural

colours, with paper prepared by him and exposed by contact behind a polychromed screen composed of a coloured-glass window. This proof was obtained twenty-eight months ago, and the colours have not yet faded.

The Society awarded a vermeil medal to M. Vieuille; a silver one to MM. Pector and Londe; and a bronze one to each of the following gentlemen, MM. Dronet, Jacquin, and Buquet. Three medals were granted for the best positive prints sent in for exhibition.

M. Grassin exhibited a negative exposed the 15th of August, 1886, at five o'clock in the afternoon, and developed the 20th of January, 1889, that is to say, two years and a half after exposure. The negative was very good; it represented a public procession. The exposure was instantaneous, a proof among many others that the latent image is not destroyed by over keeping.

M. Louis Ducos du Hauron presented a novelty in photography; whether it will be of service or not is an open question. I believe the idea is quite new. He calls the process "Transformisme." This gentleman can obtain by his process all the different effects such as are seen when a person stands in front of those concave and convex mirrors. This is the definition he gave of his process: "When rays of light are allowed to penetrate into a camera obscura, not by a single hole made through a shutter, but by the intersection of two slits made so as to throw the light in different directions, these slits being more or less apart from each other, when the rays of light are received on a screen so as to coincide with each other, the relative proportions of the image represented are completely changed." At present this appears to me to be useful only to make photo-caricatures. The idea is original, and the deformations obtained are certainly eccentric and amusing. All sorts of comical figures of a sitter can be obtained. The form of the two slits can be modified, and can take the shape of a curve, a crescent, a cross, or a hook, and so obtain, says the author, an incalculable number of transformations, either serious, scientific, pleasing, or caricatural, and that of the same sitter or model.

M. le Commandant Moessard presented an apparatus for the study of photographic lenses. By the aid of this instrument he can immediately find the exact focal length of a lens, and not only this, but what is more advantageous, the maximum or minimum of light can be measured, absorption calculated, as well as any distortion perceived, and any fault in the manufacture detected.

M. Poulene exhibited some platinum proofs, printed out without development; they were found to be inferior to proofs already exhibited which were obtained by development.

M. Schaeffer presented a hand camera of Dr. Krugener. It has the form of a book, and like all others of its kind has many advantages, such as cheapness, portability, lightness, &c.

M. Gravier exhibited a new system of fixing the moveable part of the camera which carries the ground glass. As the ground glass remains always at right angles with the bed of the camera, other systems I think are preferable. M. Gravier then informed the Society that all red glass to be employed to light up the dark room should be examined through the spectroscope. This is indeed new!

M. Tondent intended to exhibit a negative which was developed during the exposure, and explain how this was done. The President requested him to forbear until the next meeting, seeing the hour so far advanced (11.30). This is to be regretted as the communication appears to be of value. In all societies some young and badly informed member takes up the time, and often prevents some interesting subject being made public.

MM. Mario Carquero and Guillaumot, jun., presented an apparatus intended for the Paris Exhibition. They call it the photographic carriage. At one end of this carriage or rolling tram is an armchair, in which the person who desires to be photographed takes a seat. The armchair can be placed at any angle required. At the other end of the tram is a dummy, carrying the camera and a large mirror, which hides the camera from the sitter. In the centre of the mirror is a hole through which the lens of the camera protrudes. The sitter can see himself or herself in the mirror, and when a pleasing expression or a good position is obtained the sitter can set the lens or the shutter at work by pressing the india-rubber air ball fixed to the arm of the chair.

This ended the March meeting.

M. Gauthier Villars writes me that as M. Arthur Batut (who wrote an article on the means of taking photographic views and plans by means of a camera attached to a kite) desires that it should be publicly known that he was the first to propose a kite as a means to obtain photographic views from above, and as the author attaches great importance to his idea not being pirated, M. Gauthier Villars says that he should be obliged if the photographic journals would mention the fact. This is done, but I am afraid that M. Batut will not find himself alone; others I think will claim to share the glory with him. We shall see.

I am now getting quite close to the borders of Italy, and have obtained two hundred excellent negatives of the Riviera since my departure from Marseilles. On February 23 I was taking photographic pictures in the delightful gardens of Monte Carlo when the Prince of Wales arrived. I went to him, and said, "Will your Royal Highness permit one of your loyal subjects to shoot at you—(after a pause)—not with a deadly weapon, but with this harmless photographic lens?" The Prince and the Duchess of Manchester laughed heartily. The Prince answered, "Willingly; I will remain here quite still." I thanked the Prince, and told him that

at that distance the portrait would be very small, and if his Royal Highness would condescend to walk along the terrace towards my instrument I would seize the favourable moment. The Prince, in company with the Duchess, walked backwards and forwards, and I got three or four excellent negatives of him and his *suite*, as well as of his favourite dog. The Prince was thanked for his condescension.

Menton, March 4, 1889.

PROF. E. STERRING.

OXYGEN CYLINDERS.

To the Editor.

SIR,—In order to reassure your correspondent "G." and others interested, I have again seen the managing director of Brin's Oxygen Company, and he informs me that, although previously to the explosion in Dublin it was not always done, it is now the *invariable* rule to open the valve of every cylinder that goes into the works, so as to let the gas escape. As regards my arrangements with customers to credit the returned gas, I have been enabled to do so on account of having special understanding with Brin's Oxygen Company. All bottles tested by the Company have the letter B inside, and O stamped on the collar or mount of the cylinder, and, if not tested to one and a half tons pressure, the number of atmospheres are marked on, such as 70 A. Regarding the way in which a cylinder would behave in case of bursting from concussion or compression, it is considered it would do the same as one previously did that I believe was purposely broken, viz., rip up and let out the gas.

In the case of an explosion we have fortunately not more than one instance, viz., the Dublin, and there need never be another if users of gas will take the simple precaution of testing the gas before use by Professor Fleming's explosive gas tester.

The more that is known about the gas the better, and when users of gas understand the precautions taken, they will realise that they can work the limelight quite as safely as with gas bags and far more conveniently.—I am, yours, &c.,

J. H. STEWARD.

406, Strand, London, March 12, 1889.

COMPRESSED GASES FOR LANTERNS.

To the Editor.

SIR,—The numerous articles and letters recently published in England concerning the use of compressed gases for lanterns seem very strange over here, for with us the use of gas bags is scarcely known. Compressed gases have been used in this country for the past twenty years to my knowledge, and no one ever thinks of using the bags unless he has to work where the transportation of cylinders would be expensive. I have had them sent twenty miles by rail, and they are so very much better and more convenient to use, that they are worth the additional cost.

The idea seems to be prevalent in England that there is danger in the use of cylinders. We never think of danger here, and, so far as I know, there has not been an accident arising from their use. Moreover, safety jets and safety regulators are quite unnecessary. I do not say the latter are not advantageous, but I do say they are not required, and I doubt if they are useful except in regulating the steady flow of gas. Occasionally there will be a slight pop at the nozzle, or a mixture of gases may explode in the rubber tube below the attachment to the lantern, but I have only known the latter to happen once, and then when one cylinder was full and the other nearly empty.

When I was in England a few years since, I could not understand why so many people, in a country where the lantern is so much used, were working with gas bags. We have gas bags at lectures sometimes, but they are usually well in front of the lantern on the platform, and they do not always give as much light as one would like. I did not dream that there could be any objection to cylinders on the score of danger, and supposed the only reason they were not in use was that the compressed gases were not to be had. Now that they are available you should get better light than hitherto, and if the cylinders are always of two colours—red for oxygen and black for hydrogen—there is absolutely no danger in their use.

The zirconia light is now very favourably spoken of in Germany. Dr. Eder, of Vienna, uses it for photo-micrography, and recommends it highly. The zirconia is embedded in a platinum disc about five-eighths of an inch in diameter. These discs cost ten marks, and are said to improve by use. If flakes of zirconia come out they are ground fine in a mortar and pressed in again. Messrs. Schmidt and Haensch, of Berlin, make a special lantern for this light with condensers about thirty centimetres in diameter. They also make an improved form of jet, which is said to be far more efficient than those ordinarily used.—I am, yours, &c.,

National Museum, Washington, D.C.

ROMYN HITCHCOCK.

HYDROQUINONE.

To the Editor.

SIR,—In a letter printed in your issue of the 1st instant, our name occurs very frequently, and we did not expect to be charged with jealousy of our neighbour's new secret to "commercial success" with a lemon-coloured compound of hydroquinone. We consider this very unjust to us, as we are actually distributing pure and real hydroquinone of

Schering's manufacture, leaving to the whole world the chances of commercial success by the industry of making hydroquinone compounds.

A useful matter to know, it seems to us, when dealing with unaltered real or pure hydroquinone, is, "What is meant by pure hydroquinone suitable for photography?" To define this we must explain that, as with many other chemical products, there is pure hydroquinone—meaning that it is, technically speaking, nothing but hydroquinone, and the proper product for the photographer—and there is also hydroquinone of higher chemical purity called "purissimum," which is slightly more expensive, but which in photography works no better than the ordinary chemically or technically pure. Consequently we recommend Schering's pure hydroquinone to the photographer, and, as a particular secret to the commercial success of our buyers, do not encourage them to go to the greater expense for a luxury. Nevertheless, should operators fancy that the purissimum form will better secure their commercial success, we shall be happy to supply it.—We are, yours, &c.,

A. & M. ZIMMERMANN.

6 & 7, Cross-lane, St. Mary-at-Hill, London, March 11, 1889.

To the Editor.

SIR,—I have lately been in the habit of using hydroquinone developer, but find that the enamel of the developing dish has assumed a rough, uneven surface. It seems to me that this has been caused by the action of the hydroquinone, but am not sure. If any of your readers have noticed an occurrence of a similar nature, perhaps they will relate their experiences.—I am, yours, &c.,

DEVELOPER.

Swansea, March 11, 1889.

ACTION OF SOLUBLE BROMIDES.

To the Editor.

SIR,—Having noticed a very able and instructive article in this year's volume of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC, by Dr. Hill Norris, on *Action of Soluble Bromides on the Latent Image*, and as its teaching appears to corroborate a statement which I was allowed to make (though under editorial protest) in the pages of this JOURNAL of October 19 last, I ask permission to invite attention to it, and particularly to that portion of the article which seems so conclusively to show that bromide of potassium is not a *destroyer* of the latent photographic image; for, if this be taken as proved, it is a fact which gives much probability to the accuracy of my previous allegation, to the effect that, in cases of *much over exposure* bromide of ammonium had, in my experience, been found *not* to act as a restrainer at all when a carbonate of either of the fixed alkalies was used as the auxiliary of the pyro instead of ammonia; but the writer of the article referred to goes further, and proves by the evidence of experiment that bromide of potassium, under one condition at least, actually does the work of an accelerator. His words are:—"In experiments of this class we obtain evidence that, so far from the bromide of potassium having destroyed any part of the latent image, it has actually rendered it possible for the developer to bring out more of the feeble effects of light."

The practical lesson taught by these facts is that bromide may be freely used to restrain developmental action, provided the constitution of the developer be duly taken into account, for I still hold that it is far from being a matter of indifference whether we add bromide of potassium or bromide of ammonium to a developer made up of *carbonate of potassium* and pyro, for this reason, that the latter haloid would immediately start chemical changes, which would end in the liberation of ammonia, or its carbonate, and so upset the balance of the developer. This fact has been made more evident to me by the following experimental trial of *hydroquinone* which I made a short time since. Acting on the knowledge of the foregoing facts, I mixed two developers containing the new agent as follows:—No. 1. Eight grains hydroquinone; thirty-two grains sulphite of soda (crystallised); and thirty-two grains bromide of potassium, and water one ounce. No. 2 was the same in all respects, save that bromide of ammonium took the place of the potassium haloid. To a given measure of each of these I added, in turn, an equal quantity of an eight-grain solution of caustic soda, and proceeded to test their respective powers of development on two plates equally exposed, upon the same subject. No. 2 began to smell of ammonium as soon as the caustic sodium solution was added to it, as I expected it would, and for this reason I also expected that it would prove by far the more powerful developer of the two, but to my great astonishment it proved no such thing; for while in five minutes No. 1 (caustic sodium) had finished its work, No. 2 (ammonium) had not begun! When the plates left the fixing bath, No. 1 reminded me more of a good wet plate negative for clearness, vigour, and delicate gradation of details, than anything I had before made on a dry plate. No. 2, which, by the way, was quite thirty minutes in developing, was a good positive picture by reflected light, but only a stain when looked through. So it would seem that, though ammonium is perhaps a more active agent than the carbonates of the fixed alkalies, it is far less powerful than the caustic alkalies are (unless bromide of sodium happens to be a much more powerful restrainer than the potassium haloid). This, if true, is a very important and suggestive fact, which I have not seen any notice of before.

From the theoretical point of view, so large a proportion of bromide as four to one of a developing agent, which is thought by many to work

better without a restrainer, appears almost rash, but the end in this instance is a justification of the means.—I am, yours, &c.,
Leeds, March 7, 1889.

W. HANSON.

THE CONSTITUENTS OF "AZALINE."

To the Editor.

SIR,—Will you kindly find room in your JOURNAL for the results of another scientific analysis of the above compound sold by me as licensee of Dr. Vogel? It is from Dr. O. W. de Witt of Berlin, and is in complete agreement with that published by you last week by C. H. Bothamley.

TRANSLATION.

"SIR,—According to your wish I have examined the packet of "azaline" sent me, and tested it for eosine and find that there is not a trace of any colouring matter belonging to that group in it.

"The analysis was carried out in the following manner:—The contents were reduced by evaporation and the residue dissolved in water, and then acidified with sulphuric acid and shaken up with ether. This left the ether colourless, as also did the addition of ammonia.

"If ever so little eosine had been present, the solution must have shown it by its colouring. This was proved by a controlling experiment in which a small trace of eosine was purposely introduced.—I remain, Sir, yours respectfully,
DR. O. W. DE WITT.

"To Dr. H. W. Vogel, Berlin."

It is certainly to be regretted that Mr. Spiller's analysis should lead him to results entirely at variance with the finding of other men of undoubted authority and independence, specially when being confronted with his finding that eoside of silver was actually formed in the orthochromatic emulsion process as described in Attout Talfer's specification, an opinion which is at total variance with that of Dr. Eder and several other almost equally good chemical authorities.

I have only to add that the above translation is my own, made from the original letter of Dr. O. W. de Witt, which may be seen at my office.—I am, yours, &c.,
J. R. GORTZ.

19, Buckingham-Street, Strand, London, March 11, 1889.

DETECTIVE CAMERAS.

To the Editor.

SIR,—In the present and past numbers of the JOURNAL, the articles on the above have doubtless been of great interest to many of your subscribers. There are now of this class of so-called "Detective" cameras scores of different patterns, more or less complicated. During the past few months I have had frequent opportunity of inspecting a hand camera purchased by an amateur in this city. Not having seen a description of this one published or brought before your subscribers, I will endeavour to give a short description.

The camera itself is contained in a wooden case, painted dead black and the brasswork also blackened, so that there is nothing conspicuous in its external appearance, and is fitted with black leather shoulder-strap, also leather handle so as to admit of its being carried as an ordinary parcel. The plates, $4\frac{1}{2} \times 3\frac{1}{2}$, are fitted into metal sheaths, and placed into a grooved box contained within the camera, and holding twelve plates, which can rapidly be brought into position one after the other. After exposure, by moving a small handle the plate slides into a grooved box in the bottom of the camera and the next plate racked into position, an ivory indicator on the side of the camera showing at a glance what plates have been exposed. The camera has two view finders, for upright and oblong pictures. The lens being of the eury-scope class, works with an effective aperture of $f/6$, about three-quarters of an inch (covering the plate sharp with full opening). The shutter works behind the lens, and is adjustable to various speeds, one-hundredth to one-half second or thereby. For hand exposures it is fitted with a set of Waterhouse diaphragms, and can be used by screwing a hood and cap on the lens. Being entirely self-contained, and obviating as it does the annoyance of having to manipulate half a dozen slides, it should prove a boon, especially with an eury-scope lens, to admit of what is generally sadly deficient in detective cameras—light.

The maker is Mr. T. Haddow, 2, Maitland-street, Edinburgh.—I am, yours, &c.,
GASKIN WOOD.

6, St. Bernard's-row, Edinburgh, March 9, 1889.

PHOTOGRAPHING MOUNT EVEREST.

To the Editor.

SIR,—Noticing in your issue of January 4 a description of photographing Mount Everest, some particulars by others may be of interest. In 1885 I sent home some attempts of the snowy range done from Hetchal on Paget plates. Dr. Donkin, commenting on these at a meeting of the Photographic Society of Great Britain, recommended the use of isochromatic plates (vide report in your JOURNAL). In these, Mount Everest was plainly distinguished, although eighty miles off. Since then I have not had an opportunity of again trying a shot at the big mountain, as whenever I have had my camera with me it has been shrouded in mist, but have done numerous ones of Kinchinjunga, which is 28,000 feet high, from distances varying from twenty miles on the hills to over a hundred down in the plains; my best have been from one and a half to two hours after sunrise—a 12×10 Ross orthochromatic lens, stop $f/64$, drop shutter

exposure, Ilford ordinary plates or Eastman's films, and careful development; with potash. Of course a second plate has to be exposed for the foreground; but I think the best results are to be obtained in the evening, just before sunset, when in the early part of the rains the snows are occasionally illuminated in masses of pink and gold. A very good picture can be obtained on a clear moonlight night, perhaps better even than in the day; also a very interesting picture is to be got on a clear starlight night without moon. An exposure, not sufficiently long to blur the stars, will give a view of the snows if done soon after sunset, the snow retaining sufficient light to impress itself on the plate.—I am, yours, &c.,
Punkaburrie, N. Bengal, February 10, 1889.

C. R. NEWTON.

PHOTOGRAPHING IN ITALY.

To the Editor.

SIR,—Being about touring through Italy during April next, and purposing using Eastman's films, I shall be glad to know what precautions are necessary to avoid interference from police or others, beside carrying passports as recommended in the ALMANAC.

2. Also, whether Eastman's rapid or ordinary films would be best to take.

3. Would not Burton's exposure table require to be diminished by one-half?

4. Please give me a formula for a hydroquinone developer suitable for developing an occasional test cut sheet.

My banishment in Brittany must be my excuse for troubling you.—I am, yours, &c.,
N. Y. Z.

Exchange Column.

* No charge is made for inserting Exchanges of Apparatus in this column; but none will be inserted unless the article wanted is definitely stated. Those who specify their requirements as "anything useful" will therefore understand the reason of their non-appearance.

Good whole-plate portrait lens in exchange for accessories or backgrounds.—Address, T. LLOYD, 35, Earl-street, Coventry.

Wanted to exchange, several good lenses and cameras for studio chair, accessories, &c. Address, RAWSON, J. Photographer, Sudbury, Suffolk.

Rastic accessory wanted in exchange for books by Professor Tyndall.—Address, REICHT, 4, Carlton-terrace, Harrow-road, London.

Will exchange handsome quarter-chime clock for tourist camera and lens for large-sized plates.—Address, WATERMAN, Photographer, High-street, Shanklin, Isle of Wight.

I will exchange THE BRITISH JOURNAL OF PHOTOGRAPHY, from July 15, 1887, up to the present time, for cabinet turnisher or half-plate camera.—Address, J. GRIFFITHS, 12, Allen-street, Hartshill, Stoke-on-Trent.

Will exchange rapid eury-scope lens, ten and a half inch focus, $f/6$, covering 9×7 , with full opening, for rapid symmetrical twelve-inch Steinheil apianat, $8\frac{1}{2} \times 6\frac{1}{2}$, or Suter's apianat & No. 3.—Address, J. GASKIN WOOD, 6, St. Bernard's-row, Edinburgh.

For exchange, heavy cabinet rolling press (nickel plate), half-plate portrait lens by Barr, whole-plate portrait lens by Leroy, card embossing press, four dies; wanted, outdoor apparatus, cameras, and lenses.—Address, MERRAT, 4, Malgrave-road, Sutton, Surrey.

A set of tanks, 16×22 , with trowsers, &c., for carbon printing, a 7×5 optimum rapid eury-scope lens, Wilson's Quarter Century in Photography, all equal to new; wanted, portable symmetrical lenses, Dallmeyer's landscape lenses, Shew's eclipse hand apparatus.—Address, H. C. J., 7, Tadema-road, Chelsea, S.W.

Answers to Correspondents.

All matters for the text portion of this JOURNAL, including queries for "Answers" and "Exchanges," must be addressed to "THE EDITOR," 2, York-street, Covent Garden, London, W.C. Inattention to this ensures delay. No notice taken of communications unless name and address of writer are given.

WILLIAM DENISON.—At Marion & Co's, Soho-square, London.

O. R.—A gelatine so acid as your sample is not well adapted for making emulsion.

H. B. MILSOME.—If you adhere to the instructions of the makers of the films—the Eastman Company—no difficulty will be experienced.

DENIS.—Yes. A lens of the rapid class of about seven or eight inches focus will take a whole-plate group in the short space at your disposal.

S. SIDEX.—As far as we know there are no detective cameras in the market similar to yours, which, from your description, ought to be a good one.

BACKGROUND.—If with using a white background you are unable to develop a background to print white, better stop it out in the negative with an opaque varnish.

C. M. MAJOR AND OTHERS.—Referring to the formula on page 576 of our last ALMANAC, Mr. Wellington has promised to elaborate on it in the course of a short time.

R. EATON.—The form of studio will do very well, but why slope the roof backwards from the first pane of glazing to the back of the backgrounds? Better make it square.

ETHEL CONSTANCE MAY.—1. The cockling is due to the negative not being thoroughly dry.—2. No, the developer has nothing to do with it.—3. The developer does not give fog when used intelligently, according to the instructions sent by the firm mentioned.

S. BARNES.—The causes of spots on collodion negatives are so very numerous that we could not explain those in the present case unless we were present during the manipulations.

S. N. SIMMONS.—If you stick a cork upon the prong of each leg of the camera stand and connect the legs with a piece of string it will neither slip nor scratch the polished marble floor.

WORLD.—1. Daguerre was born on November 18, 1787; his process was patented on August 14, 1839; and he died on July 10, 1851.—2. Daguerre and Niepce formed a partnership in 1837.

F. R. FISHER wishes to know how best to apply a cut-out mount to a print in optical contact with glass so that when mounted with an outside glass no shadows will be cast.—This cannot be done.

C. B.—Carbonate of soda (washing soda), two and a half drachms; sulphite of soda, five drachms; dissolve in one and three-quarter ounces of water and add forty-six grains of pyro. For use, dilute with five times its bulk of water.

C. H. MUNROE (Jamestown, N.Y.).—Enamelled paper suitable for receiving a coating of collodio-chloride may be had from Oefflein & Co., 54, Berners-street, Oxford-street; Buchillott & Co., 37, Southampton-row, London; and, doubtless, many others.

STEAMER writes: "Will you kindly tell me what is the nature of the deposit or for in kettles? and can you suggest anything to put in to eliminate what is already formed? I have tried diluted hydrochloric acid, but to no purpose."—Reply: Sulphuric or nitric acid will remove the deposit, which is a carbonate of lime.

GRONIA.—1. The yellow veil can be removed by placing in a solution of alum with citric, tartaric, or oxalic acid.—2. For enlarging by artificial light, condensers are necessary to direct the light in a straight line from the negative to the objective.—If you have access to our ALMANAC of 1888 you will find a chapter, on page 273, on the use of a condenser.

R. A. L. asks the size of the smallest camera made for practical use and the dimensions and information of same.—The smallest that we know of is one made by Lancaster, the body of which consists of a series of telescopic draw-tubes which close up in a case the size of and similar to a watch, but we are not acquainted with the arrangements for holding dark slides, &c.

H. J. EASTON writes: "I shall feel obliged if you will let me know how Major Barrington Baker fixes the concave glass on to the plain sheet of glass that he mentions in his paper on *Substitutes for Condensers*, on page 426 of THE BRITISH JOURNAL PHOTOGRAPHIC ALMANAC for 1889. I have tried cement, plaster of Paris, whitelead, and indiarubber, but find the glycerine eats its way out."—By opticians' cement Major Baker doubtless means Canada balsam, such as is used by opticians in connexion with achromatic lenses.

FLORENCE writes: 1. "You say in your paper of October 19, 1888, that the Barnard Comet will be seen on January 28, 1889, and that 'there will be a chance for camera work.' Has this comet appeared, as I have seen no notice of it in any other paper?—2. Can I fasten a telescope on to a camera so as to use it in the place of my lens? If so, shall I have to take any glasses out before I can use it as a photographic lens?—1. The comet has not yet made its appearance.—2. Better use the bare object glass and make an allowance for over correction.

FILM writes: "Kindly give me some advice in stripping films. I have followed the instructions, but cannot get the skin to adhere to the film in every case, but to the cloth instead. I use an ordinary squeegee and a rubber cloth."—Your difficulty no doubt arises from not using the right side of the cloth on all occasions. If you use the rubber side next the squeegee the skin will adhere to the film, but if the rubber side be used next to the skin it will adhere to the rubber instead of to the film. Try again and let us know if you manage it satisfactorily.

ARTIST writes: "Will you kindly tell me, through your columns, of an effective method of photographing on boxwood for engraving—a process workable at night-time if possible? I have found much difficulty in preparing the white ground so that it keeps on, but I am ignorant of any process complete, so that I should be very grateful for any assistance you can give me."—Reply: Whiten the surface of the wood with a paste composed of whitelead and water, then give a coating of very thin varnish in order to "bind" the surface. We do not know of any process applicable for nightwork unless you use the carbon process, exposing during the day and transferring and finishing at night.

CONSTANT READER says: "I take the liberty of addressing a few lines to you asking for a little information respecting the working of the carbon process. I have been a carbon printer about eight years, and for the last three years have had very bad health; I have been to several medical men—they don't do me any good; they say it must be something to do with my work that affects my health. I have told them I used bichromate of potash, and they said that would not affect me. I saw in your JOURNAL a discussion on carbon printing at the West London Society, and Mr. Foxlee mentions there is danger to health in the process of developing if proper precautions are not taken. Could you inform me what precautions are necessary, and what effect the developing has on the health? For any information I shall be very grateful."—The first of some articles on the bichromate disease will be found on page 174.

CANTLE wishes the following questions answered: "1. An easy but efficient method of testing for hypo in silver prints supposed to have been thoroughly washed.—2. Will washing them in a tin or zinc vessel injure them in any way?—3. The cause of spots on a silver print. On holding the print to the light I find the gloss on all the high lights entirely gone and the surface of such parts rough and blotchy. What can be the cause?"—Replies: 1. Hang it up to dry and collect the droppings in a glass; now, in (say) a watch glass, place ten drops of thin boiled starch (cold), to this add two drops of an aqueous solution of iodine, by which a violet-blue colour will be developed; mix a little of this with ten or fifteen drops of the washing from the print, and if there be any hypo present the blue colour will be discharged, but if free from this salt the colour will remain unchanged.—2. It is desirable to give it a coating of Brunswick black before using.—3. Impossible to say definitely without seeing a print.

W. A.—Send a postal card stating hour when it will be convenient to call—Monday, Tuesday, or Wednesday—as we should like to converse with you relative to the negatives.

L. J. says: "I read with interest and profit your article on *The Reactions of Mercurial Salts on Intensifying Solutions* in the JOURNAL of January 18. I think its interest would have received addition had you been able to give a method of removing the 'sickly yellow veil over the whole negative' without causing injury to the image. I have a negative in the state described, looking almost as though it had not been fixed; probably caused, as you suggest, by 'varying from ammonia to one or other of the substances last named.'—Reply: We should not have failed to mention the remedy had a satisfactory one existed for the yellow and brown stains left after mercury intensification. If the stain be of the brown kind, caused by imperfect washing after the application of the mercury, the only chance is that it may be mercurious sulphide, which is slightly soluble in potassium sulphide; but the prospect of doing much good with that re-agent is not encouraging. But if the 'sickly yellow veil over the whole negative' is due, as is most probable, to imperfect washing after fixing, and before applying the mercurial solution, it may consist of silver sulphide, which is slightly soluble as hot concentrated nitric acid. This we did not consider worth mentioning as a remedy.

FLORENCE writes: "1. If I dip my finger in a solution of ammonia, citrate of iron, and ferriyanide of potassium, and then in H_2SO_4 , my finger will be stained blue; if I dip the stained finger in ammonia (liq. 880) the colour is taken away, but can be restored again by putting on H_2SO_4 . Will you be kind enough to tell me what chemical change takes place?—2. What quantity of K_2CrO_4 must I put to an ounce of gelatine to make it insoluble after exposure to light? also, how much H_2O must I use?—1. The ammonia most probably converts the ferrous ferriyanide which forms the stain into ammonium ferriyanide and a basic hydrate of iron. Upon the application of sulphuric acid the ammonia is again withdrawn and the original salt re-formed. In all likelihood if a thorough washing followed the ammonia treatment, so as to remove the soluble ferriyanide, the stain would not reappear.—2. Dissolve the gelatine in the proportion of about sixty grains to the ounce of water. The proportion of bichromate is immaterial so far as the ultimate result is concerned, provided a sufficient exposure be given; but bear in mind that the smaller the quantity the longer the exposure necessary, while as the proportion increases so also will the discolouration of the gelatine film by light. As it is of greater importance to obtain a colourless film than to work with great speed, you will do well to employ a minimum of bichromate, say about one grain to each ounce of solution.

PHOTOGRAPHIC CLUB.—March 20, 1889.—Smoking concert.

MR. WILLIAM ENGLAND has favoured us with two cabinet prints from flash light photographs taken respectively of the London and Provincial Photographic Association and of the technical meeting of that of Great Britain.

SCANDINAVIAN EXHIBITION.—A meeting of the photographers of Scandinavia will be held at Christiania, Norway, from June 11 to 14 of the present year, to celebrate the fiftieth anniversary of the discovery of photography, and a photographic exhibition will be held in connexion with it. The Photographic Society of Christiania, the organizers of the meeting, invite inventors of instantaneous shutters of all nations to exhibit them, and each shutter must be accompanied by a collection of ten instantaneous pictures taken with it. The exhibitor must also give his name and address, as well as a description of the lens, diaphragm plate, developer, paper, &c., employed in the production of the pictures, together with the price. His Majesty the King has placed at the Society's disposition a number of Royal silver medals, which will be awarded as prizes. The articles must be sent carriage paid to H. Ahel, Christiania, before May 15.

PHOTOGRAPHY BY GASLIGHT.—Another advance has been made in photography as the result of experiments made with a new patent of Messrs. Sugg & Co., an improved Cromartie light. At a demonstration given at the studio of Messrs. Brown, Barnes & Bell, eight lamps of the improved pattern were in use, giving a light of about forty candle-power each, and some excellent negatives were secured. The light is a modification of the ordinary "Cromartie," the process rendering it particularly actinic, and thus specially adapted to photographic work. Negatives were taken both of groups and Rembrandt heads, the results showing no perceptible difference from photographs taken by daylight. The advance illustrated by this new development in the art of photography may be imagined, for it practically renders the various firms who adopt the patent independent of the weather. The exposures varied from ten to twenty seconds. Photography by gaslight has been attempted by various firms in different parts of the country, but thorough success has not been attained until now. The experiments were made under the superintendence of Mr. R. Brown, jun., and Mr. Semmance, local manager for Messrs. Sugg & Co. Visitors to the studio or to Messrs. Sugg's can see specimens of the photographs, and they will admit they are equal to pictures produced by daylight.—*Liverpool Echo*.

THE BRITISH JOURNAL OF PHOTOGRAPHY.

No. 1507. Vol. XXXVI.—MARCH 22, 1889.

THE CRYSTAL PALACE JUBILEE EXHIBITION.

THIS Annual Exhibition has, we vain hope, come to be a permanent resident amongst us. The experience of the last year, when it was initiated, has served to remove certain elements by which a *souffron* of friction was then encountered.

Very wisely, as we think, the medal system has been suspended as regards lenses and other apparatus. The display of pictures is very large, and each exhibitor has sent his best.

Among the exhibitors in the art department are to be found the names of the Polytechnic School of Photography, Lavender, Morgan & Kidd, Frith (Reigate), Hallier, Eastman Company, Wollaston, Webster Bros., Benrose & Sons, Bedford Lemere & Co., Keene, Winter, Byrne, Gridley, Maull & Fox, F. W. Edwards, London Stereoscopic Company, Marsh, Parry, and others.

It is in the apparatus department, however, where the greatest attraction to the photographer will be found, and, as we did last year, we shall bestow considerable space to a description of the novelties to be found under this heading.

The promoters have worked assiduously and well, both in this and the pictorial division; and with the anticipation of more favourable weather than was experienced last year, it will, we hope, achieve that great appreciation from the public which its merit demands.

The manufacturers of lenses and others who make a speciality of them come out in great force. Among these we recognise Ross & Co., Dallmeyer, Taylor & Hobson, Wray, and Beck; but, indeed, lenses of one or another form are to be found in the majority of stalls of the exhibitors.

Marion & Co. have a very large display, so have, also, Eastman, Lancaster, the Stereoscopic Company, Rouch, Lawley, Sands & Hunter, Fallowfield, and Negretti & Zambra. The exhibits of Mawson & Swan, Houghton, and Stanley are also characterised by fullness and variety.

Messrs. Watson are also here in great force; Shew, Gotz, and the Photographic Apparatus Company being also well represented.

The list of exhibitors also includes the names of Mayfield, Couch, the Paget Company, Fry & Co., Thomas, Abraham, Zimmermann, The Photographic Artists' Stores, Mothershill, Skinner, and Wormwald.

Amongst specialists in lanterns are Steward, Walter Tyler, W. C. Hughes, and Noakes.

Spicer, Theobald, and the Platinotype Company are also included in the list, to which we may add that of W. Tylar, of Birmingham.

As we write this notice the catalogue has not yet issued from the press, although hourly expected.

Next week we shall speak of the various exhibits in full detail, and, as on a previous occasion, describe as amply as possible the novel features of the apparatus exhibited, which we may state is of an exceedingly high class throughout, and shows that a great advance has been made during the past twelve months.

This exhibition partakes somewhat of a jubilee or semi-centennial character as regards photography, fifty years having now elapsed since the Daguerrotype was introduced to a wondering world.

As we have already said, great credit devolves upon the organizers and managers of this exhibition.

EFFECT OF DIMINISHING THE DIAMETER OF A LENS.

SOME of our friends have of late, and in these pages, been disagreeing respecting the illumination of a plate when the light is transmitted under circumstances by which a portion is unequally cut off. Probably the few remarks we are about to make may tend to elucidate the matter, and we shall assume the lens on which the trials are being made to be a rapid doublet, working at its full aperture.

The circle of illumination or area of delineation given by such a lens will be lessened by reducing the effective diameter of either the front or the back component, whether by an annulus or otherwise. Indeed, many of the hoods of objectives of this class are of such a narrow and projecting nature as to materially circumscribe this area of illumination, from which fact may be deduced a hint by those who desire to obtain the largest possible photograph by a given lens.

While the illuminated circle is decreased by "stopping" the margins of either component, the intensity of the illumination on the plate is less affected by an annulus around the back lens than if the front one were so treated, because, taking axial rays as an instance, a bundle of these falling upon the front element will suffer convergence immediately upon their transmission, and will all pass through a back lens of slightly less diameter than the front. In this case, the diameter of the front is the measure of the intensity; but such intensity would be materially diminished were the annulus placed at the front, as when in that position the angular aperture of the combination would be reduced.

When an opaque slip is inserted equi-distant between the lenses, no light is of course transmitted, but it is surprising to what a short distance it has to be raised in order to allow the

light to be distributed over the plate, a fact which would indicate this as a favourable position for a shutter.

PRACTICAL CONSIDERATIONS IN STUDIO BUILDING.

II.

WE have assumed as an axiom that all studios should give the artist power to direct the illumination to either side of his sitter's face, that is to say if full justice is to be done to every subject. As to the plan of gaining this power by having opposite sides of the studio glazed, there is the advantage of studying the sitter's feelings and convenience, with the corresponding disadvantage of rendering the direct sun more difficult to deal with. With a studio that is built east and west (the sitter usually facing the east) this is a most objectionable mode, for one side would be in full sunlight for the greater part of the working day, and to illuminate the sitter from that side is always very troublesome, whether paper, woven fabrics, or coatings of paint be used to modify the glare. Still greater are the difficulties in this form of screening off the light entirely when the north light is in use. Beyond this great drawback lies the fact that, though the sun's direct rays may be sufficiently softened to admit of artistic effects, its heat is not destroyed, and except by an almost unworkably complicated system of *louvre* boards, the heating of the studio would be almost unsupportable. When it runs north and south, the sitter facing east or west, it is more particularly in the afternoon only when the sun gives trouble, and this mode of lighting has many advantages. We shall shortly have to more fully discuss the trouble with the sun; but will first point out some considerations regarding a double-ended studio. In the first place, unless it be of very unusual length, no approach to that favourite method of some workers, the tunnel system, is permissible, as the tunnel would have to open out at each end. There is, however, no need for any one to be troubled at this, for a tunnel very greatly restricts the opportunities of the artist—it is not a desirable form. It is further obvious that in studios of ordinary length almost the whole of one side, as regards length, will have to be glazed, for the skylight for a distance in front of the sitter of about twelve feet is considered ample; when he was placed at the opposite end of the room this light would be too far in advance to get either effective illumination or a sufficiency of it. Naturally these objections would not hold when busts and half-lengths, and with a comparatively short-focus lens, were taken. So also, when a great length of room was obtainable, the twelve feet of glass could be placed in the middle of its length and space be still left to work from either end in a good light. A double-ended studio would also require either duplicate backgrounds or moveable ones, all which considerations involve elements of expense.

In assisting at arriving at a conclusion on these points, another aspect of the subject must be looked at. Taking a studio again, built north and south, great difficulty will occur with the sun's rays in and about the summer months. But with a single-ended room it may be possible either to build against a high wall or lofty building, or, failing that, to erect a wall or other structure for the purpose of keeping the sun out. This cannot with advantage be done with the double-ended form, as, when the sitter was placed at the north end, this screen would often prevent desirable effects of illumination being obtained. It is true that excess of front light is very undesirable, but there are many cases where an obstruction

of the light in front of the sitter would be particularly unfortunate.

We would here interpolate the remark that we purposely avoid alluding to particular forms of roof, such as "lean-to," "ridge," or "sloping-front" form; we do not wish any remark to have a partisan aspect—we are aware of the strong views some photographers hold—and when the context does not exclude a particular form, what we say would be applicable to all shapes.

We have said so much of the difficulties the sun's rays place in the way of the photographer, that it may be well to describe them for the benefit of those who hitherto have not been so troubled. They are not of much account in the winter months, and are confined mainly to the discomfort of heating the room to excess, and to the real injury to work by either shining into the lens or the more subtle evil of illuminating the atmosphere between sitter and lens. We need scarcely say that the very finest sunbeam whose path lay in such a course would destroy all brilliancy of shadows, while if a broad beam of light passed, the work would be worthless till the rays were screened off, or, at any rate, softened by the interposition of some diaphanous substance. We well remember being asked for advice by a fairly practised hand in regard to certain parallel streaks that made their appearance at times upon his negatives, and which we diagnosed as effects of light. We may conclude our remarks for the present occasion by explaining their cause and how they were prevented. The studio was a sloping front facing due north (the sitter having his back to the sun), and it was built against a high building, the sash-bars running from overhead forwards. This was the very position to minimise or destroy the sun's injurious action; but the building was not quite high enough, for during a month or two in the middle of summer, for a few minutes, comparatively speaking, in the middle of the day, the sun's rays just passed over the building and shone into the studio. The streaks on the negatives were simply the breaks in the sunbeams caused by the bars of the skylight. It was thus quite possible for the effect to remain some time unnoticed, through the combined effect of cloudy days or photographic work not going on at the particular time of day when only the effect could be produced.

The cure was as follows: Immediately overhead a wooden awning projecting about four feet was built against the lofty building spoken of, and at the highest point attainable; and in addition to this a screen was built inside the studio to receive the residuum of beams and prevent them illuminating the atmosphere in front of the lens, some judgment being required to place it so as to answer the purpose without interfering with the field of view. This incident is fairly instructive as showing the defects incident to a particular aspect and how it was found possible to master them.

MANY professional photographers evidently do not attach much importance to the permanence of their work, that is if one may form an opinion from the evanescent character of the pictures shown as specimens at, and issued from, some establishments. We are not now alluding to the prints produced by those houses who do the work at low prices, as here it may be somewhat excusable, if an excuse be admissible for sending out pictures which are certain to prove fugitive, when the bestowal of a little more time and care would ensure those of a more permanent character. The houses to which we here specially refer are some of those which charge the highest prices, and yet care but little for the permanence of their pictures. "A thing of beauty is a joy for ever," so says the proverb, but this clearly does not apply to photographs, or at least the majority of

them. The chief aim amongst professionals at the present day, it would seem, is to produce a thing of beauty. But for how long it shall be a lasting "joy" is a question which a large proportion of photographers completely ignore.

PASSING through one of the fashionable thoroughfares at the West End a few days back, we noticed at a leading photographers an enlarged portrait—life-size or thereabouts—highly finished in oil colours. We cannot state the price that would be charged for a similar picture, though we think we may safely say it would not be less than twenty guineas at this establishment. The picture was on a photographic basis, but of what kind we are unable to say. However, the picture had cracked badly, and the cracks were confined to those portions where the photograph would be the strongest—the shadows, hair, dress, and the darker parts of the background. The lighter portions of the flesh, although they were thickly painted with body colour, were intact. This would rather indicate that the fault rested with the photographic basis. There are many works by the old masters in existence, which have been painted nearly as many centuries as, probably, this picture has been years, which show less signs of deterioration. But this is the point. Here is an expensive picture, badly deteriorated, which is publicly exhibited as a specimen by an establishment of reputation. This naturally leads one to imagine that here, at least, durability in the work is but of secondary consideration.

STRICTLY as the Copyright Act is, it is manifest that it is being infringed, and in a somewhat barefaced manner, too. Some months back we alluded to this matter, and mentioned that photographic reproductions of some of the most popular engravings of the present day were being publicly sold. Only last week we saw an itinerant vendor in the street offering photographic copies of most of the leading modern engravings, including such works as *Christ leaving the Priesterium*, *Too Late*, *The Peace Maker*, *The Ruling Passion*, *A Disgrace to his Family*, *For the Safety of the Public*, &c. &c. The copies were of good size—from twelve to fifteen inches—and mounted on large sheets of cardboard. The price asked for them was but two shillings and threepence each, followed by the query, "Well, what will you give?" This sum seems ridiculously small considering the penalties incurred under the Copyright Act. Some of the prints were slightly stained or otherwise damaged, although they appeared to have been made from good negatives. It may, therefore, well be imagined that these were rejected prints, and that perfect ones are to be had elsewhere at a higher and more remunerative price.

THE present is an excellent time for securing cloud negatives. During the latter part of March and the beginning of April, as well as in September, good cloud effects, as a rule, can be more readily obtained than at any other period of the year. Perhaps, however, for grand studies of clouds the autumn would take the palm, but for clouds for printing into other pictures those obtained in the spring are usually better in accord with a sunny landscape, such as those for which most artists require them. At the present time there is not much to be done out of doors, and the time may be profitably spent in securing a goodly number of cloud negatives for future use, and these may now be obtained without difficulty. A good variety of cloud negatives is an acquisition to every photographer. Nothing looks much worse than to see, as one frequently does, the same clouds introduced into several different pictures. This, however, is often met with, and even in different peoples' work, when commercial cloud negatives are employed.

IN taking sky negatives, judgment must be used in the development that they are not made too dense, or with too great contrasts. In developing, the amateur often makes them too strong. Hence in the printing, in order to obtain all the detail, they become too pronounced. Clouds, it should be borne in mind, are introduced as an adjunct to the picture, but if they are made obtrusive it goes without saying that they will completely spoil the effect. In taking studies of clouds, if they are to be printed and used as such, the negatives should be

made of a different density from those which are to be used for printing into landscape pictures. In seascapes, representing storms or gales, stronger cloud negatives than would be desirable with ordinary landscapes are not only permissible, but advantageous. But usually, with this class of subject, the natural sky may be obtained in the seascape negative.

AMATEURS should now be prospecting for the coming season, both as regards the apparatus they will adopt, and the class of subjects they intend to make a speciality. We strongly advise every one, whatever be the form of apparatus decided upon, to have with it the means of taking stereoscopic pictures. There is no question but that the stereoscope now promises, within a brief time, to again become a popular thing. Every camera of the half-plate size and larger should therefore be arranged for taking binocular pictures, particularly as the slight modification, practically, neither increases the bulk or weight of the apparatus.

THE resuscitation of the stereoscope is being largely brought about by the popularity of the optical lantern. The experience gained by amateurs, in making transparencies for this instrument has, of course, availed them in the production of similar pictures for the stereoscope. We shall be surprised if the majority of the slides which in the future will be made for this instrument are not transparencies. There is a certain charm about a transparency when viewed in the stereoscope which it is impossible to obtain in a print on paper. With the different commercial lantern plates now in the market, almost any colour or tone may be obtained.

IN the Daguerreotype days an extensive business was done in stereoscopic portraits. We doubt if at the present time one portrait photographer in a score could take a stereoscopic picture if called upon to do so by a customer. If the stereoscope regains its former status, we imagine that stereoscopic portraits will again be in considerable demand. Possibly professionals will do well to be prepared.

IT is imagined by many that the wheel or Robinson trimmer, which is so largely employed for cutting paper masks, can only be used for round or oval shapes. But this simple piece of apparatus will answer quite as well for square or oblong, provided a narrow slot—the eighth of an inch or so, according to the diameter of the wheel—be cut in each of the angles of the metal "shape." Even when cutting rectangles with a knife—when the cutting is done from the inside of the templet—it is convenient to have a slight slot in the angles, as then the corners may be more clearly cut than is usually done by amateurs.

A RECENT issue of the *English Mechanic* gives an illustration of a patent gas utiliser, which, if all said of it be true, should be particularly useful in the dark room. Whatever of improvements may have taken place in many studios, there yet remains a large number where the developing chamber is not much more than a box, with an atmosphere in its normal state not very healthful, but with even its one solitary gas jet burning is positively unhealthful. This Spong's Patent Gas Utiliser should reduce the consumption and, of course, consequent fouling of the air to two-thirds; for the journal in question quotes Mr. H. Leicester Greville, chemist to the Commercial Gas Union, as stating that, with gas at ten-tenths pressure, the mean increase of light is 52.9 per cent., and also of its own experiments states that the illuminating power of any fish-tail burner is increased by its use.

IN addition to the display of art subjects and apparatus at the Crystal Palace, the daily lantern entertainments, which last year proved so great an attraction, will be repeated, competitive and other photographic slides being enlarged on the screen to thirty feet in diameter by special limelight apparatus, presided over by Mr. W. Brooks. A grand *soirée* will also be held on Thursday evening, the

29th instant, when many objects of great historical interest will be exhibited. Addresses, with lantern demonstrations, will also be given on the history and progress of photography. Visitors to the Palace will be admitted without extra charge.

ON THE VALUATION OF HYDROQUINONE.

II.

Now with regard to the presence of sulphur or sulphur compounds. We have recently been told that in Germany a considerable percentage of sulphurous acid has been found in the yellow hydroquinone. Immediately on the appearance of that statement I made a search, and found sulphur certainly, in the form of SO_2 , as I took it, which I estimated to be present in the proportion of about .26 per cent. Now Mr. Levy says he found sulphur, but no sulphurous acid, "so that the sulphur must be due to sulphuric acid." From this result, and the latter conclusion especially, I must dissent on several grounds.

I think there can be no question of the fact that the yellow colouration is caused by contact, at some period of its existence, of the white hydroquinone with sulphurous acid or an acid sulphite; whether the colour necessarily disappears with the last trace of the free sulphurous acid, or on its conversion into sulphuric acid, I am not able to say, but if the yellow tint be permanent then Mr. Levy may be correct, inasmuch as the sulphurous acid originally present may, in his sample, have been oxidised to sulphuric acid. But that sulphuric acid is not the original "impurity" or preservative agent is open to very easy demonstration. I made a solution of sixteen grains of white hydroquinone in one ounce of a mixture of sulphuric acid, s.g. 1.84 and water in the proportions of 1 : 7, that is to say, one drachm of strong sulphuric acid to the above quantity. The solution remained for several hours perfectly colourless, but on the addition of a minute crystal of sodium sulphite the characteristic tinge of yellow was given to the solution by the liberation of a trace of sulphurous acid. This I think dismisses the supposition that sulphuric acid, and not sulphurous, can be the original preservative.

I repeat that on this point there can be little doubt. In the process of preparing hydroquinone by the action of sulphurous acid upon quinone the original yellow colour of the latter is gradually removed, and when the conversion is complete a colourless solution of white hydroquinone remains. If, however, the treatment with sulphurous acid be continued, the solution again becomes yellow, and when saturated with SO_2 yields by evaporation yellow crystals, which are found to contain definite proportions of hydroquinone and sulphurous acid, and which has been called sulphite of hydroquinone. The proportions are three of hydroquinone to one of SO_2 , or between sixteen and seventeen per cent. of the latter. Upon heating, the SO_2 is given off and white hydroquinone remains.

I may remark, *en passant*, that when a definite compound exists containing as much as sixteen per cent. of sulphurous acid, the use, for beneficial purposes, of so small a quantity as one quarter per cent. as a preservative in "permanent" hydroquinone scarcely justifies its condemnation on the score of impurity.

My own view is, that not only is sulphurous acid in some form the preservative employed—either free or in the form of an acid sulphite, possibly of ammonia—but that it is present, and not sulphuric acid in the crystals themselves. I say this for various reasons. I have tried to show that SO_2 is necessary to the production of the yellow colour, and, considering the ease with which that colour is removed, either by heating or by recrystallisation, either of which will remove the SO_2 , it seems undoubted that the colour is dependent on the actual presence of the acid.

But besides that, by fusing a few of the crystals on platinum foil, or in a hard glass tube, the presence of sulphurous acid is patent to the smell. We cannot reasonably suppose that sulphur itself is present to account for it, nor can I conceive that it is due to the decomposition of sulphuric acid, since the fusion of hydroquinone occurs at a temperature nearly 300°Fahr. below the boiling point of sulphuric acid, and we know the latter can be distilled unchanged, so that a far higher temperature would be necessary for its decomposition. It is

true that by heating platinum foil in the presence of vapour of sulphuric acid the latter is split up into oxygen and sulphurous acid, but a red heat is necessary; it is true also that strong sulphuric acid boiled with certain metals—silver, copper, mercury, for instance, or even with carbon in the form of charcoal—yields SO_2 , and the action of the sulphuric acid upon a portion of the hydroquinone accidentally carbonised in fusion *might* produce the smell of SO_2 , but I do not think any of the conditions are sufficiently favourable to account for its formation in that way.

But, leaving the fusion test as allowing a loophole for doubt, I will give other reasons for rejecting the sulphuric acid theory. Let a strong, hot, aqueous solution of the yellow crystals be made, and I think, to nerves of ordinary sensitiveness, the presence of free sulphurous acid—either wholly free, or partly combined, as in the case of an acid sulphite—will be clear enough. Or, if any doubt remain, let a small quantity of citric acid be added, when the smell will become more intense and undeniable. The last experiment may be made with a cold alcoholic solution, and points rather to the presence of an acid sulphite, since it is difficult to see how the addition of citric acid can give greater prominence to a quantity of SO_2 , already free, though in the case of a sulphite it brings the whole of the combined acid in evidence. Mr. Levy and I agree in the entire absence of sulphites of the fixed alkali, but it is not improbable that the acid ammonium salt may be present, and minute traces would be difficult to value, except as sulphurous acid. Or it is possible that the so-called sulphite of hydroquinone itself may be added in small quantity as the preservative.

However, there can be no ground for supposing that, if sulphuric acid were present, it would be reduced to sulphurous by mere solution, or by the addition of citric acid. In fact, so far as I can see, there is not only no reason for saying that the sulphur *must* be due to sulphuric acid, but there is, on the contrary, every evidence that it is not, and cannot be.

There is one other sulphur compound which would form a theoretically good preservative for hydroquinone, but which, though actually employed, would not be likely to be found in the crystallised product in its original state. I allude to the acid known variously as thio-sulphurous or hydrosulphurous, and which is formed by the deoxidising action of metallic zinc upon aqueous sulphurous acid or a sulphite. This is one of the most powerful reducing and bleaching agents known, far exceeding sulphurous acid in this power, but it is exceedingly unstable, absorbing oxygen, and reverting to the state of sulphurous acid within a few minutes of preparation. It was with this preparation that, years ago, I first noticed the peculiar yellowing action, in conjunction with pyro solution, which occurs in precisely the same manner as with hydroquinone, though with pyro I have been unable to get the yellow crystals. If hydrosulphurous acid, or one of its salts, were the agent originally used, it would only exist in the crystals as sulphurous acid or as a sulphite.

I do not intend in this article to say a word about the value or otherwise of this preservative agent; the series of experiments I have on hand have for their object, *inter alia*, this very point, and this brings me to the final remark I have to make on Mr. Levy's paper. It is extremely valuable as a chemical examination, and useful to the photographer as showing to what extent the products he is supplied with agree with their theoretical composition. But it says nothing about the practical side of the question, or whether the white or the yellow, the English, French, or German make of hydroquinone constitutes the best developer.

The finest "malt" vinegar would take but a poor place either for purity or strength as "acetic acid," but I fancy most professed cooks would look very much askance if asked to use the pure acid, "solid at 50° ," for their purposes; and so with the photographer and hydroquinone. What gives him the best result is the best product, call it what you may.

I do not know that any great advantage will accrue from them, but the idea of my experiments seemed to me an interesting and possibly useful one, viz., the testing not only of different samples and makes of hydroquinone, but also different alkalies and proportions in order to find the absolute reducing power of each sample and each mixture upon silver bromide. In addition, I am comparing the results with pyro tested in the same manner, taking note of the variations

and peculiarities of the character of the reduction so as, if possible, to solve some of the anomalies of development with hydroquinone.

It is needless to say that such trials need care and take time, so that I cannot very well "rush" the results. But so soon as I have fairly placed myself in the position of being able to do so I will report my results.

W. B. BOLTON.

ECHOES.

"CHEMICAL Vignetter" seems rather a misnomer for Mr. Robert Morrison's substitute for the ordinary vignette glass or card screen, though the contrivance is undoubtedly a good one, and capable of producing results far superior, as far as softness is concerned, to the mechanically graduated glasses.

But I would suggest a far simpler method of construction than that given, and one that I have frequently myself used when requiring vignettes of special or extraordinary form. This consists in utilising the printing frame instead of the camera for the purpose of making the negative or reverse vignette, and if only a single one be required it may with the least possible trouble be made direct, and in every case the gradation is quite as perfect and fully as much under control as when the camera is used.

Proceed as follows:—In a piece of opaque cardboard or sheet zinc cut an aperture a little smaller than the vignette required, and of suitable shape, bearing in mind that the more gradual the shading is to be the smaller must be the opening, and *vice versa*. Also that the opening should be proportionately a little longer in shape than the finished vignette is required, as the graduation "spreads" relatively more in the direction of the breadth than the length. On no account serrate the edges, as this has merely the effect of enlarging the aperture without in the least affecting the gradation. Fix this mask on an ordinary printing frame in just the same manner as if for an ordinary vignette print; in fact, the processes are so far quite identical. Run a tack or small wire nail into each of the corners of the printing frame and attach four pieces of thin twine or stout worsted, tying them in a knot at about three feet from the frame so that the latter may be suspended in a horizontal position, face upwards. Having so hung the frame, arrange so that the light from a gas flame, lamp, or candle falls upon the surface of the vignetting card at a more or less acute angle, according to the degree of softness required, remembering that the softness increases in proportion to the distance of the screen from the sensitive film, and to the smallness of the angle at which the light falls.

In the dark room itself the whole process can be most conveniently worked. Place a sensitive plate or piece of sensitive paper—positive answers quite well—in the printing frame, suspend it as described, with the aperture covered with a piece of ground glass, cause the whole to revolve slowly but uniformly, which it will easily do for some time owing to its mode of suspension, and turn up the gas or other light for the required number of seconds. On development a tint of the most exquisite gradation will result when after one or two experiments the proper adjustments of the screen and light have been obtained. The *cliché* thus produced will be opaque in the centre, shading off to clear glass, and can be used as a negative from which to reproduce any number of clear-centred, vignette glasses. If only a single one be required for a particular purpose, instead of the opaque mask with centre aperture, attach a piece of opaque paper of suitable shape to the centre of a sheet of ground glass, or, better still, of thin Rives's paper, using this as the vignetting screen, when a clear-centred vignette will result. In this case the opaque centre must of course be larger than the vignette required and broader in proportion.

I have found this plan often very useful, and the whole preparations may be made in five minutes, when a "vignetter" of particular shape is suddenly required. By making an opaque, centred *cliché*, and reproducing it by simple contact printing on ordinary albumenised paper, which is finally rendered translucent by means of oil vaseline, any number of vignettes may be had at a merely nominal cost; indeed, every negative may have its own permanently attached.

The genial Mr. William Cobb commenced modestly his dissertation on *Art in Relation to Photography* by fearing that he would find

himself "rowing in the same boat" with others who had previously "made a shipwreck" of the subject. Fortunately in such cases of "shipwreck" the "fatalities" are comparatively few, the waters are always shallow, and if only the rocks—breaches of the "strict canons of art"—be avoided, the unfortunate "mariner" may generally flounder into his depth again.

I remember, many years ago, an old and well-known photographer (still living) expressing himself to the effect that "photographers who talk art" generally make fools of themselves. If this sweeping assertion be partially true it is because of the difficulty pointed out by Mr. Cobb of defining what art is. If the rules of pure art be difficult to discover, how much more so must it be to fix them when complicated and mixed up with the tools, appliances, materials, and, above all, the hopes, aspirations, and difficulties of the photographer?

Photographic art productions have always been regarded from two entirely distinct standpoints—that of the photographer and that of the artist; and the former, when he aspires to the latter designation, has been generally too prone to make too much allowance for his difficulties, while the artist, on the other hand, totally ignores them. The artist is perhaps, after all, correct, for art is art no matter what its source.

The triumphs of the art photographer in past days have, no doubt, been meritorious in the highest degree from the photographic point of view, but as comparable with the real masterpieces of art as a child's slate pencil sketch with a finished water colour, or a portrait by a Chinese artist with a Millais or Holl. They belong, in fact, to a distinct category.

But at the present time far greater facilities exist for the production of really "artistic effects" by means of the camera than were available in the days of Hejlander. But let us—those of us at least who aspire to be artists as well as photographers—drop the plea that we are hampered by our tools and should therefore be handicapped in the competition with painters. I reckon that, fifty years after the "discovery" of painting, brushes, colours, and canvas were not as perfect, nor were the "canons of art" so well understood as even they are at the present day, so there is plenty of time before the photographer need begin to feel ashamed that he cannot beat the artist on his own ground. Such, at least, is how it appears to me; and if in saying so I have added to the number of shipwrecked ones, or those who have made fools of themselves, I cannot help it. Such occurrences are almost invariably rather unlooked-for than wilful.

But Mr. Cobb is scarcely happy in one or two of his references. For instance, to that of the "historical apron of fig leaves." That, I take it, was scarcely in any form a work of art, but most emphatically and common-placedly (pardon the word) utilitarian. It may have been a useful and durable garment, and, considering the absence of manufacturing facilities at the period, worthy of a medal, or at least honourable mention, in an industrial exhibition. It might even possess the "priceless value" Mr. Cobb sets on it as a "relic," but not as a work of art, for I judge it could scarcely be much more ornamental than the gentleman found his raiment under similar circumstances of necessity when having had his clothes stolen while bathing he was escorted home wrapped in a newspaper. JUNIUS.

WEIGHTS AND MEASURES.

[A Communication to the Photographic Club.]

AMONG the numerous difficulties which beset the path of the would-be photographer, none is perhaps as perplexing as the much vexed question of weights and measures.

Even those who have long since mastered the various manipulations which tend to the production of the finished photographic picture, and who can boast of long experience in the art, are at times puzzled by the formulæ which are proposed in the photographic periodicals.

A very superficial glance over the developing formulæ which have been compiled by Messrs. Lyonel Clark and Ferrero, and in which they have reduced all quantities to grains and minims per ounce, will show what complication is brought about by the most empirical system of writing formulæ now in use.

No doubt every plate maker who prints a formula on his plate

boxes has excellent reasons for recommending the proportions indicated, but as there is absolutely no possibility of comparing one developer with another, so as to modify the one in use to suit the prescriptions set forth on the new brand of plates about to be tried, the only resource is to make up a lot of developer especially for the purpose, and here the photographer is placed at a disadvantage. When using the solutions to which he is accustomed he knows perfectly what effect a drop or two more of this or that solution will have on the development. With the unfamiliar mixture he is very far from having the same amount of certainty.

All developers are made up of a limited number of chemical substances, the proportions only being varied. It seems, therefore, natural that standard solutions should be adopted in the same manner that interchangeable elements have been introduced into machinery and apparatus. If this were the case, nothing would be easier than to suit the developer to the brand of plate in hand. All the formulæ being given in parts of standard solution, it would only be necessary to measure out the number of parts recommended by a given plate maker, to obtain at once the developer wished for.

A step has been made in that direction by the introduction of ten per cent. solutions. Unfortunately, plate makers have not modified their printed formulæ to suit this departure, and besides, with our existing system of weights and measures, a ten per cent. solution seems to be a very difficult thing to describe accurately, if one is to judge by the many discussions which have, from time to time, appeared in the technical papers.

A great deal might be said and written on the subject of percentage solutions, and I must ask you to excuse me if I go into details which may seem elementary to you. I am desirous of putting things as clearly as I can, and I believe that clearness is inseparable from completeness.

I will now define a "standard solution." This is a solution of which a given volume contains an exact and constant quantity of a chemically active agent. Standard solutions have long been used in chemical analysis, but it is only justice to give Friedrich Mohr the credit for having established volumetric analysis on a scientific basis by introducing a systematic method of compounding the solutions used.

The standard or normal solution of a reagent is always made such that one litre at 60° Fahr. shall contain exactly the hydrogen equivalent of the chemical compound to be used. Thus, if hydrogen is taken as one, the hydrogen equivalent of caustic potash will be fifty-six, and it will therefore be sufficient to dissolve fifty-six grammes of caustic potash in one litre of distilled water at 60° Fahr. to obtain a normal solution of caustic potash. It will at once be seen that as such a solution is always prepared under precisely the same conditions, its chemical action will always be constant for a given volume.

Mohr employed the decimal system of weights and measures. He, however, proposed that special weights should be constructed, each one being exactly equal to the weight of a given chemical to be dissolved in one litre of water. Thus for caustic soda a weight equivalent to forty grammes was to be constructed.

As this system introduced new weights it did not find much favour among chemists, and it has not been adopted. The decimal system is besides so easy to employ that the want of any novel or improved system was not felt.

In England Mr. Griffin and Mr. Acland introduced a decimal system based on the gallon, each author denominating differently the various subdivisions. This system is still in use for certain Government tests, and is certainly a great advance on the old fluid measure.

One of the greatest sources of uncertainty in making up a formula is the want of information as to the system of weights which the author has used. We are told in all the books on the subject that in photography the apothecaries' weights are to be used. Many writers, however, appear to have based their formulæ on the avoirdupois system. Again, it is often difficult to determine whether the author means that the solid chemicals shall be dissolved in a given volume of water, or that the solution is to be made up to that volume.

Standard solutions would do away with all these causes of doubt, and nothing would be easier than to compound by their use any ratio of reducer to alkali.

One of the great advantages of the decimal system of weights and measures, is that the weight of a given volume of water, expressed in cubic centimetres, is always a definite number of grammes. It is, therefore, quite easy to make a solution of a proposed strength. One is only limited by the coefficient of solubility of the chemicals to be dissolved.

It may be argued that the decimal system is but little known in

England, and less used. Also, that an Act of Parliament would be requisite to bring it into universal use. Photographers have long since appreciated the value of scientific methods, and it may be said that day by day the development of the negative is becoming an operation requiring more and more precision and scientific correctness. Sooner or later the photographer will, therefore, have to resort to more precise methods of making his solutions, and there does not seem to be any reason why he should not follow the example of other English scientific people who have adopted the gramme, the litre, and the centigrade thermometer. They have been able to do this without waiting for an Act of Parliament, why should he not do likewise?

It has also been said that the introduction of a new system of weights and measures would necessitate new apparatus, of which the cost might be an objection. I do not think that the expense incurred would be very serious, as a very small quantity of apparatus would be required.

Messrs. Townson and Mercer have kindly placed at my disposal the glass measures and sets of weights which are on the table, and these, I believe, are more than what may be wanted by even the most fastidious. Without wishing to describe the decimal system in its entirety, it may be well to remind you that the cubic centimetre weighs exactly one gramme when the temperature is 4° centigrade. The measures before you have, however, all been graduated at a temperature of 15½° centigrade or 60° Fahrenheit. This is more convenient, as the temperature in a laboratory is generally about that mark. It is, therefore, possible to make up the various solutions with absolute correctness as to volume if care is taken to have the water at 60°. This is, however, not actually required in photography. I strongly recommend the use of stoppered measure glasses for the larger volumes, such as would be used in making up the stock solution. The dry chemicals are put in the test mixer, and a quantity of warm water added. This can be well shaken up without any loss, and the chemicals much more quickly dissolved than when the usual stirring rod is resorted to. When all is dissolved the solution is allowed to cool, and the bulk made up with cold water. In making a solution of pyrogallie acid the sulphite of sodium would be dissolved in this manner, the liquid, after cooling, poured over the pyrogallie acid, and then returned to the test mixer, to be made up to bulk with cold water. This method would have the advantage of exposing the pyrogallie acid as little as possible to the air. With the test mixers and an ordinary pair of scales solutions can readily be made up to any desired strength. There only remains now to decide upon the strength most suitable for photographic purposes, taking into account the fact that the existing concentrations to which operators are accustomed must not be altered in any great degree. For pyrogallie acid I propose that 50 grammes should be made up to 500 cubic centimetres. The cubic centimetre would then compound to '1 gramme, or about 1½ grains. Looking through the tables of developers above referred to I find that 1½ grains to the ounce represents about the average.

Therefore, 2 cubic centimetres made up with water to 50 cubic centimetres, would represent very nearly the usual 2 ounces of developer for a half-plate.

For soda the average is about 16 grains per ounce. The solubility of anhydrous carbonate of sodium being 20 parts in 100 parts of water, I propose to make this solution by dissolving 100 grammes to a volume of 500 cubic centimetres. The cubic centimetre would then be equal to '2 grammes. I think that this dilute solution would be an advantage since development could be made very gradual with it. Five cubic centimetres would correspond to 15½ grains.

Other solutions could be adjusted in the same manner. I hope that the rather dry subject which I have dealt with to-night has not tired you, and if the few crude suggestions made lead some more experienced operator than myself to take up the subject, I consider that some advance will have been made towards furthering an improvement of which every one must feel the necessity.

ADOLPHE M. LEVY, C.E.

ABSTRACT OF E. H. JAKUES' PAPER ON NORWAY.

[Communicated to the Birmingham Photographic Society.]

IN the course of a few introductory remarks, Mr. Jaques said:—

"He had much pleasure in again describing and illustrating some portion of Norway, a country alike interesting to travellers and the amateur photographer. On this occasion he proposed to deal with the district traversed by their mutual friend, Mr. William Rooke, and himself in June and July last, namely, the Valdres route between
